So far we established we can specify fully an SVM model even when the number of variables greatly exceeds the number of training samples (e.g., number of variables in the thousands with number of samples in the dozens). But can the classification performance under such conditions be good? We will give here an intuitive explanation why this is indeed the case. First, note that we are interested in good predictive performance for cases previously undiagnosed and sampled independently of the training sample from exactly the same population of patients. In statistical terminology, we say we wish to minimize "i.i.d. generalization error." Hence, as a first step, we need a good method to estimate the generalization error. Statistical sampling theory provides such an unbiased estimator of this generalization error in the form of the *leave-one-out error* (see later in this chapter). It is easy to see that the leave-one-out error is strictly a function of the support vectors (the nonsupport vectors will always be classified correctly). It can be shown easily that the leave-one-out-error has upper bound $s/(2d)$ where s is the number of support vectors and d is the total number of training data instances (patients). Assume for illustrative purposes that in our example three support vectors are selected in all of the leave-one-out splits; in this case the expected generalization error (the error if we were to use the same method on a very large set of data) is at most $3/38 = 7.9\%$. As the number of training instances grows, the generalization classification performance approaches the large sample optimal.

This example and discussion demonstrate that within the framework of SVMs it is possible to build classifiers even when the number of predictors is orders of magnitude larger than the available sample size (something not possible in classical regression-based classifiers); and such classifiers can exhibit very good classification performance.

Feature Selection and Construction

Feature selection is pursued because (1) a decreased set of variables will reduce the computation time from impossible to feasible, (2) feature selection may allow researchers to better understand the domain, (3) collecting a reduced set of predictors may be cheaper, and (4) collecting a reduced set of predictors may be safer (e.g., a blood sample versus a biopsy specimen). Feature selection methods are typically of the *wrapper* or the *filter* variety. Wrapper algorithms perform a search in the space of all possible variable subsets and evaluate each visited subset by applying the classifier for which they intend to optimize the variable selection. Common examples of search strategies are hill climbing (forward, backward, and forward-backward, simulated annealing, branch-and-bound, and genetic algorithms).[32,35] Filter approaches select features on the basis of shape of the data, called its joint distribution. The optimal variable set can be discovered effectively with newer algorithms under mild distributional assumptions[6,49,50] and allows optimal feature selection under those assumptions.

Once a variable subset has been identified, both traditional statistical classifiers and newer methods such as SVMs can be built using only the selected variables. A variant of the variable selection problem is the *feature* (or variable) *construction* problem in which one tries to transform the original variable set into a new set of variables for which building classifiers are easier to compute or fewer samples are required. Examples of such methods include principal components analysis for array gene expression-based diagnosis, and clustering and peak detection as preprocessing to mass spectrometry diagnostic model building.[28]

Clinical Examples

Gene array expression measurements have been used to (1) classify lung cancer patients as having adenocarcinomas or squamous carcinomas,[10] and metastatic cancer or non-metastatic cancers; and (2) distinguish between normal and cancer samples.[4,5] Classification of adenocarcinoma versus squamous carcinoma[3] was accomplished using array comparative genomic hybridization (CGH) data. Models predictive of prognosis for patients with various stages of lung cancer[9] have been built using gene expression data. Patients with leukemia were classified as having acute myelogenous versus acute lymphocytic leukemia using array gene expression data,[25] while models for predicting clinical outcome of breast cancer have been developed.[51] Models were built to detect early prostate cancer and discriminate it from BPH and normal prostates using mass spectrometry data.[1,40] Mass spectrometry has been used to detect ovarian cancer,[39] to detect malignant cutaneous melanoma,[21] and to detect transitional cell carcinoma of the bladder.[53]

These applications are only a small sample of a large number of molecular-profiling clinical bioinformatics models that apply advanced computational techniques on mass-throughput data to address questions of prevention,

diagnosis, treatment selection, and prognosis. A multitude of computational methods not covered here have also been explored in such problems.

Model Validation

In the neural net example above, it was clear that a method that is created and performs well on a training set of data may not perform well when another data sample is encountered. Hence a "validation" (test set) of data is needed to estimate how the classifier would perform in real life.

A variety of procedures are available to assess a model's true expected performance: split sample validation, cross-validation, jackknifing, and bootstrapping.

In split-sample or hold-out validation the data set is split randomly into different subsets: training and test sets. The training set is used for learning, typically estimating the model's parameters; the test set is used to assess the model's expected performance on future sets of data and its ability to generalize. Random case assignment is necessary to obtain representative groups. The split-sample approach works well for large sample data sets and, as long as the number of cases available in each subset is sufficient, will avoid overfitting and generate unbiased estimates.

However, small sample size data sets, in the range of 50 to 200 cases, are more common. With small sample data sets, using all cases for training and then using the same cases for testing is not permissible because biased (overly optimistic) results will be obtained. The cases in the training and test sets are no longer independent of each other. Computer-intensive statistical approaches, such a cross-validation, jackknifing, or bootstrapping are available and are the preferred evaluation methods that overcome some of the limitations inherent to sets with small sample sizes. These procedures are based on resampling theory and have the advantage that all cases can be used for training and testing. In resampling theory the observed data set becomes the underlying population from which samples are drawn repetitively with replacement. The samples are used to estimate parameters of interest.

Cross-validation is used to estimate the generalization error of a model or to compare the performance of different models. K-fold cross-validation divides a data set into k different subsets of equal size n. The validation procedure includes k runs and applies a "round-robin" approach. During each run one of the k subsets is left out and used as the test set while the remaining subsets are used for training the model. Leave-one-out cross-validation is present if k equals the sample size (i.e., each subset includes only one case). The selection between leave-one-out cross-validation and k-fold cross-validation depends on the situation. The former is preferred for continuous error functions, whereas the latter is preferred for determining the number of misclassified cases. A frequent value for k-fold cross-validation is $k = 10$.

Similar to leave-one-out cross-validation, jackknifing also involves omitting one case from the entire subset. However, jackknifing is applied to estimate the bias of a statistic of interest rather than the generalization error.

Bootstrapping involves the repetitive drawing of random samples with replacement from the observed population and computing statistics. A complete bootstrap in an observed population with eight variables would require the calculation of bootstrap statistics for $8^8 = 16{,}777{,}216$ samples, quite a computer-intensive process. Therefore bootstrap samples are usually limited to hundreds or thousands of drawings.

The validation procedures based on resampling theory mimic the theoretical process of repetitive sampling from an unobserved population; however, the samples are drawn from an empirically observed population rather than a theoretical, unobserved one. The limitation of resampling procedures is the representativeness of the observed population; unless the observed population is representative, the ability to generalize the model remains biased.

COST EFFECTIVENESS AND OUTCOMES RESEARCH

Optimal use of the laboratory requires examination of both the cost of obtaining the result and the value or quality of the information obtained. Determining the quality of various procedures in medicine has been a subject of increasing interest over the last 2 decades. Some key aspects of value received are the amount of improvement in health care, the extent to which testing is consistent with the wishes and expectations of patients, and the degree to which testing addresses social concerns as embodied in laws and regulations.

The Clinical Laboratory Improvement Act of 1967 (CLIA '67) and the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88) mandate quality control and external quality assurance programs in large part as an effort to address social concerns regarding the quality of testing results. Only indirect measures of the quality of testing in terms of individual or population health benefit are available. The major instruments for measuring the quality of a healthcare intervention, including laboratory testing, are healthcare outcomes. Outcomes can be defined as the state or condition of an individual or population that is a result of antecedent medical care. In an effort to examine these issues and as a result of CLIA '88, the Centers for Disease Control and Prevention initiated the Evaluation of Quality of Laboratory Practices and Standards program, which partners with various groups to investigate the relationship between quality issues in the laboratory (e.g., proficiency testing, quality assurance, and personnel) and their effect on patient outcomes.[11] By tying specific analytical procedures and performance to patient outcome, it may be possible to directly trade off the increase in cost associated with achieving increased precision and accuracy with actual patient benefit. At this point, however, results are very preliminary and few conclusions can be made.

Another approach to quantifying health outcomes is to estimate the cost implications of a true-positive diagnosis and the costs of false-positive, false-negative, and true-negative results. One can calculate a weighted average of cost across all possibilities to determine whether a testing strategy is sensible. The decision threshold can be changed to maximize the benefits or to minimize the costs.[7,38,46,55]

An example of the issues involved can be found in the outcomes analysis of screening for prostate cancer. Prostate screening programs are increasing each year, partially accounting for a 600% increase in radical prostatectomies between 1984 and 1990.[37] For each man who dies each year from prostate cancer, there is a much larger number whose prostate cancer progresses slowly, never causing any morbidity. Screening is expensive and the iatrogenic side effects of surgical treatment for prostate cancer are significant. As a result of these observations, studies have called into question the overall cost effectiveness of prostate screening.

This question is amenable to outcomes analysis. One can examine the dollar costs per life year saved using two strategies. In the first strategy, assume that men age 45 through 75 undergo a screening PSA evaluation. If the screening PSA is greater than 4 μg/L, they are followed up by transrectal ultrasound evaluation and digital examination. If either of the subsequent tests is positive, a biopsy would be performed, and patients with positive biopsies would undergo radical prostatectomy. In the second strategy, there is no screen, and when prostatic carcinoma clinically appears, patients are treated using radiation and hormonal therapy for symptomatic relief. The literature provides the estimated number of life years lost, the patients' normal expected life span, and the expected life span based on the two strategies. Using methods described in more detail elsewhere,[30,45] the cost per life year saved can be computed. The costs of follow-up treatment for surgical side effects (e.g., incontinence and impotence) can be calculated from published frequencies of occurrence. A graphical depiction of the two strategies is shown in Figure 15-10, which is called a decision tree.

Figure 15-11 demonstrates that the overall cost per life year saved decreases with an increasing PSA screening decision threshold. The data for men 75 years of age are not graphed, because it is estimated that there would be a net decrease in life expectancy at all decision levels. The most benefit is achieved for younger men at decision thresholds that are very specific (i.e., have very few false-positive results). The data are limited in not examining all decision thresholds. It would appear likely that using even higher decision thresholds would result in still more cost/life year gains.

But is the program worth it at any decision level? One can estimate the relative worth of the program by comparing the proposed cost per increased life year with those of other programs. After calculating the present-day value of money invested in the future (called "discounting"), the overall cost per life year is higher than is generally spent on other programs, making the use of general prostate screening difficult

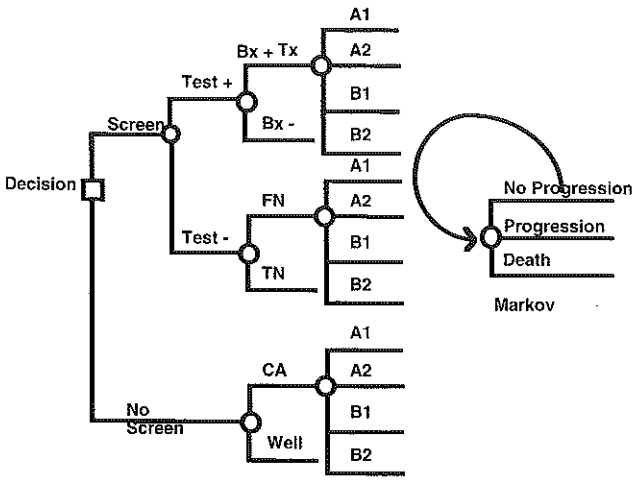

Figure 15-10 The decision tree shows alternative strategies that branch at the *square box*. The *lower* branch assumes no screening, and disease is treated symptomatically as symptoms appear. The *upper* branch evaluates with a screening program, followed by radical prostatectomy for biopsy-positive cases. *A1* through *B2* represent different cancer stages. The Markov model is an algorithm that evaluates costs and life years gained as patients sequentially stay unchanged, progress, or die each year. It repeats for 15 years. *(From Shultz EK. Multivariate receiver operating characteristic curve analysis: Prostate cancer screening as an example. Clin Chem 1995;41:1253.)*

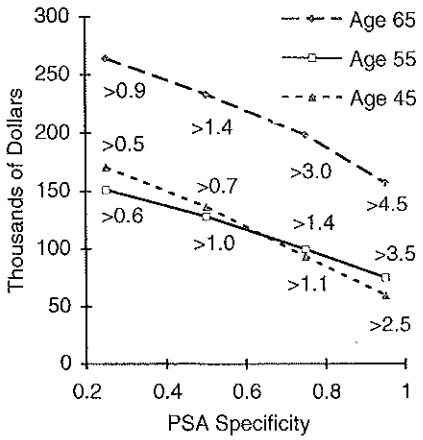

Figure 15-11 Cost per incremental life year in nondiscounted dollars. The decision thresholds on the plot are in micrograms per liter. This is marginal cost per additional life year relative to no screening. In screening, the most cost-effective strategy results from using different decision levels based on the patients' ages. Younger patients have the most to gain from screening, but the overall cost is still high in all groups. *PSA*, Prostate-specific antigen. *(From Shultz EK. Multivariate receiver operating characteristic curve analysis: Prostate cancer screening as an example. Clin Chem 1995;41:1254.)*

to justify.[31] Others have proposed quality-adjusted life years (QALY) as a more suitable yardstick. A QALY was developed to try to quantify the relative value of life spent with decreased functionality to a life year with no functional limitation (e.g., how much is a life with chronic incontinence

worth compared with a normal life?). However, in the previous analysis, the conclusion would be strengthened if a man found incontinence or impotence less desirable than full health, so use of QALYs is not necessary for the general conclusion.

As new types of procedures, increased test sensitivity, and therapeutic alternatives become increasingly available, the challenge will be to skillfully combine medicine, laboratory expertise, and analytical thinking in the guiding of laboratory practice. Maximizing benefits given a limited set of resources requires a well considered approach to the selective improvement of test accuracy and precision and to the interpretation of test results.

CHAPTER 16

Establishment and Use of Reference Values

Helge Erik Solberg, M.D., Ph.D.

THE CONCEPT OF REFERENCE VALUES

Medicine is an art and a science in the service of fellow human beings. To improve the health of their patients, physicians (1) collect empirical data, (2) interpret these data using scientific knowledge and professional experience, (3) make decisions concerning diagnoses, (4) recommend preventive measures, and (5) execute therapeutic actions. There is a fundamental limitation in this activity as absolute health does not exist. Health is necessarily a relative concept.[20]

Interpretation by Comparison

To say that health is *relative* implies that the condition of individuals must be related to something. Data collected during the medical interview, clinical examination, and supplementary investigations must be interpreted by *comparison* with reference data. The physician does this when making a diagnosis. If the condition of the patient resembles what is considered typical of a particular disease, the physician may base the diagnosis on this observation (positive diagnosis). This diagnosis is made more likely if observed symptoms and signs do not fit the patterns characterizing a set of alternative diseases (diagnosis by exclusion). Such disease patterns are examples of reference data necessary for the medical interpretation. Also, the different degrees of health have their set of characteristics that serve as reference sources for judging the health of an individual.

The process of medical interpretation by comparison may be more or less formalized. Some diagnoses are recognized by an intuitive assessment based on "clinical experience." Others are based on reasoning using advanced knowledge of normal and pathological anatomy, physiology, and biochemistry and of other relevant areas of medical science. Sometimes, the evaluation is of a qualitative nature; in other cases, it may be quantitative. The decision making may even be computer assisted, using rules based on the laws of probability and statistical techniques or on formalized medical knowledge (expert systems, artificial intelligence).

The interpretation of medical laboratory data is an example of decision making by comparison. We therefore need *reference values* for all tests performed in the clinical laboratory, not only from healthy individuals but from patients with relevant diseases.

Ideally an observed value *in an individual* should be related to *relevant* collections of reference values, such as values from healthy persons, from the undifferentiated hospital population, from persons with typical diseases, and from ambulatory individuals, and previous values from the same subject.[66] A patient's laboratory result simply is not medically useful if appropriate data for comparison are lacking.

Normal Values—An Obsolete Term

Historically the term *normal values* was frequently used to refer to medical data used for purpose of comparison. However, the use of the term often leads to confusion because the word "normal" has several different connotations.[48] For example, three medically important but very different meanings of "normal" are given in the following:

1. *Statistical Sense:* Values are often qualified as "normal" if their observed distribution seems to follow closely the theoretical *normal distribution* of statistics (i.e., the Gaussian probability distribution). Somehow this use of "normal" has misled people to believe that the distribution of biological data is symmetrical and bell shaped like the Gaussian distribution. But on closer examination, this is usually found not to be the case. To exorcize the "ghost of Gauss," Elveback and colleagues recommend not using the term *normal limits.*[15] For a similar reason, the term

normal distribution should also be avoided and replaced by the term *Gaussian distribution.*

2. *Epidemiological Sense:* Another meaning of "normal" is illustrated by the following statement: It is "normal" to find that the concentration of triglycerides in serum is between 0.6 and 2.4 mmol/L, whereas it is considered "abnormal" to have a serum triglyceride concentration outside these limits. Here a more exact statement would read as follows: approximately 95% of the values obtained, when measuring the concentration of triglycerides in sera collected from individuals considered to be healthy, is included in the interval 0.6 to 2.4 mmol/L. The obsolete concept of "normal values" partly carried this meaning. Alternative terms for "normal" in this sense are "common," "frequent," "habitual," "usual," and "typical."
3. *Clinical Sense:* The term "normal" is also often used to indicate that values show the absence of certain diseases or the absence of risks for the development of diseases. In this sense, a "normal value" is considered as a sign of health. Better descriptive terms for such values are "healthy," "nonpathological," or "harmless."

Because of the confusion resulting from the different meanings of normal, the term "normal values" is now considered obsolete and should not be used.

To prevent the ambiguities inherent in the term *normal values,* the concept of *reference values* was introduced and implemented in the 1980s.[21,66] At first glance, the substitution of *reference values* for *normal values* appears to be unimportant, but on closer scrutiny this change in nomenclature is an important step toward establishing a scientific basis for clinical interpretation of laboratory data.[71]

Terminology

The International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) recommends the term "reference values" and related terms, such as "reference individual," "reference limit," "reference interval," and "observed values."[34] The definitions given below and the presentation in the following sections of this chapter are in accordance with the IFCC recommendations.*

The definition of *reference values* is based on that of the reference **individual**[34]:

an individual selected for comparison using defined criteria.

As mentioned above, for the interpretation of values obtained from an individual under clinical investigation, we need appropriate comparison values. To provide such values, we must select suitable individuals. The characteristics of the individuals in each group chosen for comparison should be clearly defined. We must specify their age and gender, the conditions for the specimen collection, and whether they should be healthy or have a certain disease. The definition of a reference individual also covers cases in which the individual under clinical investigation is his or her own reference, as discussed in a later section on subject-based reference values.

A **reference value** may then be defined as[34]:

a value obtained by observation or measurement of a particular type of quantity on a reference individual.

If, for example, we measure the concentration of triglycerides in sera collected from a group of reference individuals selected for comparison according to a sufficiently exact set of criteria, the triglyceride results are our reference values.

The **observed value** is defined as[34]:

a value of a particular type of quantity, obtained by observation or measurement and produced to make a medical decision. Observed values can be compared with reference values, reference distributions, reference limits, or reference intervals.

Or rephrased: an observed value is the laboratory result obtained by analysis of a specimen collected from an individual under clinical investigation. Some call such values "test values," but the word "test" in this term is ambiguous (a laboratory test? a statistical test?), and it should be avoided.

The IFCC also defines other terms related to the concept of reference values: reference population, reference sample group, reference distribution, reference limit, and reference interval.[34] Some of these terms are introduced in later sections of this chapter.

Types of Reference Values

In practice it is often necessary or convenient to give a short description associated with the term reference values, such as "health-associated reference values" (close to what was understood by the obsolete term *normal values*). Other examples of such qualifying words are "diabetic," "hospitalized diabetic," and "ambulatory diabetic." These short descriptions prevent the common misunderstanding that reference values are associated only with health.

We may further distinguish between subject-based and population-based reference values. *Subject-based* reference values are previous values from the same individual, obtained when he or she was in a known state of health. *Population-based* reference values are those obtained from a group of well-defined reference individuals and are usually the type of values referred to when the term "reference values" is used without any qualifying words. This chapter deals primarily with population-based values.

The body of this chapter discusses population-based *univariate* reference values and quantities derived from them. If, for example, we produce, treat, and use separate reference values for cholesterol and triglycerides in serum, we have two sets of univariate reference values. The term *multivariate*

*A note on the literature: The Expert Panel on Theory of Reference Values of the IFCC has produced a series of six recommendations on the establishment and use of reference values.[34] A 1989 review by Solberg and Gräsbeck[66] gives in-depth information on this topic.

reference values denotes that results of two or more analytes obtained from the same set of reference individuals are treated in combination. The serum cholesterol and triglyceride values may be used, for example, to define a bivariate reference region. This subject is addressed in a later section.

Requirements

Certain conditions apply for a valid comparison between a patient's laboratory results with reference values[14]:

1. All groups of reference individuals should be clearly defined.
2. The patient examined should sufficiently resemble the reference individuals (in all groups selected for comparison) in all respects other than those under investigation.
3. The conditions under which the specimens were obtained and processed for analysis should be known.
4. All quantities compared should be of the same type.
5. All laboratory results should be produced using adequately standardized methods under sufficient analytical quality control (see Chapters 14 and 19).

To these general requirements one may add others that become necessary when the more advanced techniques for decision making are applied.[71]

6. The stages in the pathogenesis of the diseases that are the objectives for diagnosis should be demarcated.
7. The clinical diagnostic sensitivity and specificity, the prevalence, and the clinical costs of misclassification should be known for all laboratory tests used.

SELECTION OF REFERENCE INDIVIDUALS

A set of *selection criteria* determines which individual should be included in the group of reference individuals.[34,66] Such selection criteria include statements describing the source population, specifications of criteria for health, or the disease of interest.

Often, separate reference values for each sex, different age groups, and other criteria are necessary. Our group of reference individuals may therefore have to be divided into more homogeneous subgroups. For this purpose, we need to specify rules for the division, called stratification or *partitioning criteria.*

It is important to distinguish between selection and partitioning criteria. First, we apply the selection criteria to obtain a group of reference individuals. Thereafter, we may divide this group into subgroups using partitioning criteria. Whether a specific criterion (e.g., gender) is a selection or a partitioning criterion depends on the purpose of the actual project. For example, gender is a selection criterion if reference values from female subjects only are necessary.

Concept of Health in Relation to Reference Values

There is an obvious requirement for health-associated reference values for quantities measured in the clinical chemistry laboratory. But the concept of health[20] is problematical; much confusion may arise if the selection criteria for health are not clearly stated for a specific project.

The World Health Organization has defined health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." This is an attempt to define *absolute health,* but as such, absolute health is never attained.

Thus in the context of reference values, we need a more modest concept of health. Past experience has taught us that health is a *relative concept.* It is possible to be ill in one respect and well in another; what is considered healthy in a developing country may be judged to be rather unhealthy in Western Europe and North America, and so on.

Furthermore, the diagnosis of health cannot be based solely on excluding pathology. This fact, which has been named the *privative concept of health,* may cause difficulties. If no signs of disease can be demonstrated, uncertainty remains, because such signs might be detected on closer examination. The "feeling" of health is not a reliable criterion because of its subjectivity. In addition, an individual may try to conceal an illness for various reasons (e.g., to qualify for life insurance).

When producing reference values, we should ask ourselves, why do we need these values? How are we going to use them? To what extent does the intended purpose of the project determine how we should identify health? In short, we need a *goal-oriented concept of health.*

Gräsbeck suggested the following **general definition of health,** which summarizes the relative, privative, and goal-oriented aspects discussed previously[20]:

Health is characterized by a minimum of subjective feelings and objective signs of disease, assessed in relation to the social situation of the subject and the purpose of the medical activity, and it is in the absolute sense an unattainable ideal state.

Strategies for Selection of Reference Individuals

Several methods have been suggested for the selection of reference individuals. Table 16-1 shows three pairs of concepts that may be used to describe a sampling scheme. The concepts of each pair are mutually exclusive. For example, the sampling is either direct or indirect. One may, however, combine one concept from several pairs to obtain a more exact description. For example, the selection may be direct, a posteriori, and nonrandom.

The merits and disadvantages of these strategies are described in the following sections. It is not possible to recommend one sampling scheme that is superior in all respects and applicable to all situations. One must choose the optimal approach for a given project and state clearly what has been done.

Direct or Indirect Sampling?

Direct selection of reference individuals (see Table 16-1) is the only method that agrees with the concept of reference

TABLE 16-1 Strategies for Selection of Reference Individuals

Direct	*Individuals* are selected from a parent population using defined criteria.
Indirect	The individuals are not considered, but certain statistical methods are applied to analytical *values* in a laboratory database to obtain estimates with specified characteristics.
A priori*	A direct method (see above) in which individuals are selected for specimen collection and analysis if they fulfill defined inclusion criteria.
A posteriori	A direct method using an already existing database containing both analysis results and information on a large number of individuals. Values of individuals fulfilling defined inclusion criteria are selected.
Random	A process of selection giving each item (individual or test result) an equal chance of being chosen.
Nonrandom	A process of selection giving each item an unequal chance of being chosen.

**Note:* The terms a priori and a posteriori signify in this context "before" and "after" and refer to when inclusion criteria are applied.

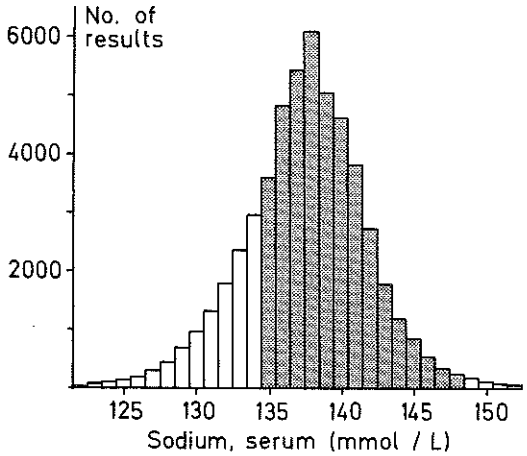

Figure 16-1 Distribution of sodium concentrations in serum obtained in a routine laboratory. The histogram shows the distribution of 53,128 serum sodium concentrations measured in consecutive clinical specimens during a 6-month period in 1982 at Rikshospitalet, Oslo, Norway. The shaded area is within health-associated reference limits as determined by a direct method (193 healthy adults of both sexes).

values as recommended by the IFCC,[34] and it is the basis for the presentation in this chapter. Its only disadvantages are the problems and costs of obtaining a representative group of reference individuals.

These practical problems have led to the search for simpler and less expensive approaches. The *indirect* method has become rather popular.[5,21] It is based on the observation that most analysis results produced in the clinical laboratory seem to be "normal." Figure 16-1 shows one example from the author's laboratory. As can be seen, the values of the serum sodium concentration have a distribution with a preponderant central peak and a shape not too far from that of the Gaussian distribution. The underlying assumption of the indirect method is that this peak is composed mainly of *normal values.* The advocates of the method therefore claim that it is possible to estimate the *normal interval* if we extract the distribution of *normal values* from this part of the distribution. *Normal limits* determined by the indirect method on the basis of the distribution shown in Figure 16-1 would, however, obviously be biased compared with the shown health-associated reference limits. (Note that the term "normal" is here used intentionally to distinguish between the concepts of *normal values* and reference values.)

Several mathematical methods have been used to extract the distribution of *normal values* from routine laboratory data.[5,21]

The indirect method, however, has several important deficiencies. The two major ones are as follows:

1. The estimates of the lower and upper *normal limits* depend heavily on the particular mathematical method used and on its underlying assumptions.
2. The indirect method destroys the scientific basis for obtaining and comparing reference values. The results for each hospital would depend on the characteristics of the hospital's patient group at that particular time. These results would vary not only across hospitals but for the same hospital at different times. The outcome would be a mass of unstable values for each analyte.

Hospital databases may, however, be used for the establishment of reference values that are fully concordant with the IFCC recommendations.[38,64] The requirement is that laboratory data be combined with information stored in clinical databases (i.e., to apply a direct sampling strategy instead of the distribution-based indirect method). Laboratory results are to be used as reference values only if stated clinical criteria are fulfilled. One may define criteria for selecting individuals who have a specified state of health or the disease for which reference data are necessary. Usually certain constraints are also imposed on the use of their laboratory results, such as allowing only one result of each analyte under study from each selected individual. Such reference values have one advantage over those based on direct sampling from other types of populations: hospital-based reference values are ideal for the interpretation of results from hospitalized patients because they are produced under similar conditions.

A Priori or A Posteriori Sampling?

When carefully performed, both a priori and a posteriori sampling (Table 16-1) may result in reliable reference values.

The choice is often a question of practicality. Both require the same set of successive steps, but the order of some of these operations differs depending on the mode of selection, a priori or a posteriori.[21]

The first step in the process of producing reference values for a laboratory test should always be the collection of quantitative information about the sources of biological variation for the analyte studied. A search through relevant literature may give the required information (see Chapter 17).[58,72] If the relevant information cannot be found in the literature, pilot studies may be necessary before the selection of reference individuals is planned in detail.

Serum sodium is an example of a biological analyte that is affected by only a few sources of biological variation. However, the list of factors may be rather long for other analytes, such as serum enzymes, proteins, and hormone.

It is important to distinguish between controllable and noncontrollable sources of biological variation. Some factors may be controlled by the standardization of the procedure for preparation of reference individuals and specimen collection (see a later section of this chapter). Other factors, such as age and gender, may be relevant partitioning criteria. The remaining sources of variation should be considered when defining the criteria for the selection of reference individuals.

The a priori strategy is best suited for smaller studies. Possible reference individuals from the parent population are interviewed and examined clinically and by selected laboratory methods to decide whether they fulfill the defined inclusion criteria. If the decision is positive, specimens for analysis are collected by a standardized procedure (including the necessary preparation of the individuals before the collection).

The a posteriori method is based on the availability of a large collection of data on medically examined individuals and measured quantities. Well-planned studies by centers for health screening or preventive medicine may provide such data. It is important that the data be collected by a strictly standardized and comprehensive protocol concerning the sampling from the parent population, the registration of demographic and clinical data on participating individuals, the preparation for and execution of specimen collection, and the handling and analysis of the specimens. If these requirements are met, values may be selected after application of the defined inclusion criteria to the individuals found in the database. The selection of individuals from large hospital databases (see earlier discussion) is another example of the application of an a posteriori method. In this case, however, the quality of data may be lower than in well-planned population studies.

A study performed in Kristianstad, Sweden,[7] highlights a practical problem often met when selecting reference individuals: the number of subjects fulfilling the inclusion criteria may be too small. In that study, only 17% of the participants were accepted by the criteria used, leaving an insufficient reference sample group. The frequency of exclusion was higher among women and in the older age groups.

There are two possible solutions to this problem:

1. The exclusion criteria may be relaxed. As already discussed, the set of relevant sources of biological variation differs among different analytes. One may define a minimum set of exclusion criteria for a given laboratory test. In the Kristianstad study, the complete group of individuals could probably be used for establishment of reference values (e.g., serum sodium), and most of the individuals would be acceptable for the determination of reference values for several other analytes.[7]
2. Another design of the sampling procedure could reduce the practical problems and costs of obtaining a sufficiently large group of reference individuals. The Kristianstad study showed that 75% of the excluded subjects could have been identified using only a simple questionnaire.[7] In the upper age group, this percentage was even higher. Therefore a preliminary screening of a large number of individuals from the parent population, using a carefully designed autoanamnestic questionnaire, would result in a much smaller sample of individuals to examine clinically and by laboratory methods. If 3000 individuals had been prescreened in Kristianstad, and if only the individuals remaining in the reduced sample were subjected to a closer examination, a group of 240 reference individuals would have been obtained.

The two modifications of the protocol may also be combined.

Random or Nonrandom Sampling?

Ideally, the group of reference individuals should be a random sample of all the individuals fulfilling the defined inclusion criteria in the parent population. Statistical estimation of distribution parameters (and their confidence intervals) and statistical hypothesis testing require this assumption.

For several reasons, most collections of reference values are, in fact, obtained by a nonrandom process.[26] That means that all possible reference individuals in the entire population under study do not have an equal chance of being chosen for inclusion in the usually much smaller sample of individuals studied. A strictly random sampling scheme is in most cases impossible for practical reasons. It would imply the examination of and application of inclusion criteria to the entire population (thousands or millions of persons) and then the random selection (e.g., conduct a raffle) of a subset of individuals from among those accepted.

It is important to realize that we do not obtain a random sample, in the strict sense, if we start by selecting individuals randomly from the entire population and then apply inclusion criteria to sort out the subset of individuals fulfilling these criteria, even though this may be the best approximation we can hope to obtain. Usually the situation is less satisfactory. A sample of reference individuals obtained by selecting among blood donors, persons working in a factory,

BOX 16-1 Examples of Exclusion Criteria for Health-Associated Reference Values*

Diseases

Risk Factors
- Obesity
- Hypertension

- Tobacco

Specific Physiological States
- Pregnancy
- Stress
- Excessive exercise

*The box lists only some major classes of criteria. It should be supplemented with other relevant criteria based on known sources of biological variation (see Chapter 17).[58,72]

or the hospital's staff, or by selection from hospital databases, is definitely not random sampling of the possible reference individuals in the general population.

The conclusions are obvious: (1) we have to use the best reference sample we can possibly get, all practical considerations taken into account; and (2) data should be used and interpreted with due caution, remembering the possible bias introduced by the nonrandomness of the sample selection process.

Selection Criteria and Evaluation of Subjects

The selection of reference individuals consists essentially of applying defined criteria to a group of examined candidate persons.[34] The required characteristics of the reference values determine which criteria should be used in the selection process. Box 16-1 lists some important criteria to consider when the production of health-associated reference values is the aim.

The question of which *diseases* and *risk factors* to consider for exclusion of individuals is difficult (see the discussion on the concept of health earlier in this chapter). The answer lies partly in the intended purpose of establishing reference values; the project must be goal oriented.

The definition of *obesity* is problematical. It might be based on a known or assumed contribution to the risk for development of a specified disease. Scientific data of this type are, however, seldom available for the studied population. Another possibility for establishing obesity is to use upper limits based on weight measurements in different age, gender, and height groups of the general population, using, for example, the national age-, gender-, and height-specific mean weight +20% as the upper limit. National differences are, however, great. Tables of optimum or ideal weights have been published by life insurance companies, and they may be more appropriate for delineation of obesity than this formula.

Similar problems affect the definition of *hypertension* in relation to the establishment of health-associated reference values and exclusion criteria based on *laboratory examinations.* It has been argued that we might be lost in a circular process when we use laboratory tests to assess the health of subjects who are subsequently to be used as healthy control subjects for laboratory tests. But actually there is no difference, in this context, between measuring the height, weight, and blood pressure and performing selected laboratory tests, provided that these laboratory tests are neither those for which we shall produce reference values nor tests that are significantly correlated with them.[20]

It is particularly difficult to define selection criteria when establishing reference values for a geriatric population.[16] In higher age groups it is "normal" to have minor or major diseases and to take drugs. One solution is to collect values at one time and to use the values of survivors after a defined number of years.[20,50]

Usually the clinical evaluation of candidate individuals is based on an anamnestic interview or questionnaire, a physical examination, and supplementary investigations. Anamnestic and examination forms tailored to the requirements of the actual project facilitate the evaluation and document the decisions taken.

Partitioning of the Reference Group

It may also be necessary to define *partitioning criteria* for the subclassification of the set of selected reference individuals into more homogeneous groups (Box 16-2).[34] We shall return in later sections to the question of determining when stratification of the reference sample group is necessary and justified. The number of partitioning criteria should usually be kept as small as possible to obtain sufficient sample sizes to derive valid estimates.

Age and *gender* are the most frequently used criteria for subgrouping because several analytes vary notably among different age and gender groups (see Chapter 17).[16,58,72] Age may be categorized by equal intervals (e.g., by decades) or by intervals that are narrower in the periods of life where greater variation is observed. In some cases it is more convenient to use qualitative age groups, such as postnatal, infancy, childhood, prepubertal, pubertal, adult, premenopausal, menopausal, or geriatric. Height and weight could be used as criteria for categorizing children.

Additional factors are discussed in Chapter 17.[58,72]

SPECIMEN COLLECTION

Several preanalytical factors influence the values of biological quantities, such as the concentration of components in

HLA, Human leukocyte antigen.

blood and in other specimens and the amount excreted in feces, urine, or sweat. This topic is covered elsewhere (see Chapter 17).* In this discussion, we only highlight aspects of special relevance to the generation of reliable reference values.[4,34]

Preanalytical standardization of the preparation of individuals before specimen collection, the procedure of specimen collection itself, and the handling of the specimen before analysis may eliminate or minimize bias or variation from these factors. This reduces biological "noise" that might otherwise conceal important biological "signals" of disease, risk, or treatment effect.

Two Philosophies of Standardization

Preanalytical procedures used before routine analysis of patient specimens and when establishing reference values should be as similar as possible. In general it is much easier to standardize the routines for studies of reference values than those used in the daily clinical setting, especially when collecting specimens in emergency or other unplanned situations. Thus two approaches have been suggested:

1. Only such factors that may be relatively easily controlled in the clinical setting should be part of the standardization when reference values are produced.
2. The rules for preanalytical standardization when producing reference values (Table 16-2) should also serve as ideal standards for the clinical situation. It has been shown that it is possible to apply these rules rather closely in the clinical setting for both hospitalized and ambulatory patients.[66] The same philosophy is the basis for recommendations concerning routine blood specimen collection.*

Either philosophy is, however, concordant with the concept of reference values, provided that the conditions under which reference values are produced are clearly stated.

Standardization Schemes

The magnitudes of preanalytical sources of variation are clearly not equal for different analytes (see Chapter 17).† It could therefore be argued that we should consider only those factors that cause unwanted variation in the biological quantity for which we want to produce reference values. Body posture during specimen collection is, for instance, highly relevant for the establishment of reference values for nondiffusible analytes, such as albumin in serum, but irrelevant for establishment of serum sodium values.[17]

On the other hand, several constituents are routinely analyzed in the same clinical specimen. It would therefore be impractical to devise special systems for every single type of quantity.[66] For that reason, three standardized procedures for blood specimen collection by venipuncture have been recommended[4,21]: (1) collection in the morning from hospitalized patients, (2) collection in the morning from ambulatory patients, and (3) collection in the afternoon from ambulatory patients. Table 16-2 summarizes these procedures.

Such schemes of standardization have to be modified depending on local conditions and necessities and on the intended use of the produced reference values. Published checklists[34,66] may be helpful in the design of a scheme.

A special problem is caused by drugs taken by individuals before specimen collection.[36,73,80] We may distinguish between indispensable and dispensable medication. The latter type of drugs should always be avoided for at least 48 hours. The use of indispensable drugs, such as contraceptive pills or essential medication, may be a criterion for exclusion or partitioning.

In emergency or other unplanned clinical situations, even a partial application of the standardized procedure for collection has been shown to be of great value.[21]

The Necessity for Additional Information

The clinical situation often is different from a controlled research situation; specimens have to be taken during operations, in emergency situations, or when patients are unwilling or unable to follow instructions. Therefore the clinician needs additional information for the interpretation of a patient's values in relation to reference values obtained under fairly standardized conditions.

An *empirical approach*[66] is to produce other sets of reference values, such as postprandial values, postexercise values,

*References 17, 21, 22, 58, 66, 72, 79.

*References 3, 4, 34, 41, 46, 49.

†References 17, 21, 22, 58, 66, 72, 79.

or postpartum values.[21] Such a method, however, is very expensive and does not cover all situations that could possibly arise.

There is another and more general solution to the problem, called the *predictive approach*.[66] Starting from a set of ordinary reference values and using quantitative information on the effect of various factors, such as intake of food, alcohol, and drugs; exercise; stress; or posture, we could estimate "expected reference values" that fit the actual clinical setting (see Chapter 17).[58,72]

More studies of such effects are needed, especially for the combined effect of two or more sources of variation. Is, for example, the combined effect of alcohol and contraceptive drugs on γ-glutamyltransferase activity in serum less than, equal to, or greater than the sum of their individual effects?

ANALYTICAL PROCEDURES AND QUALITY CONTROL

Essential components of the required definition of a set of reference values are specifications concerning (1) the analysis method (including information on equipment, reagents, calibrators, type of raw data, and calculation method), (2) quality control (see Chapter 19), and (3) reliability criteria (see Chapter 14).[21,34]

Specifications should be so carefully described that another investigator can reproduce the study and the user of reference values can evaluate their comparability with values obtained with the methods used for producing the patient's values in a routine laboratory. To ensure comparability between reference values and observed values, the same analytical method should be used.

It is often claimed that the analytical quality should be better when determining reference values than when producing routine values. This may be true for accuracy; all measures should be taken to eliminate bias. The question of imprecision is more difficult because it depends partly on the intended use of the reference values. Increases in analytical random variation result in widening of the reference interval.[21] For some special uses of reference values, the narrower reference interval obtained by a more precise analytical method may be appropriate. However, this is usually not true

TABLE 16-2 Standardization of Preanalytical Factors in the Establishment of Reference Values for Adult Individuals

The Day Before Specimen Collection	
Food	Ordinary intake; last meal before 2200 hr
Alcohol	Maximum of one small bottle of beer (or equivalent of other beverage) taken with a meal
Abstinence	No solid food or tobacco and maximum of one glass of water after 2200 hr
Subjects Lying in Bed; Collection in the Morning	
Rest	Bed rest from 2200 hr until collection; a short visit to the toilet allowed, but minimum of 1 hr before collection
Collection	Between 0700 and 0900 hr (record time); supine position with the arm approximately in the horizontal plane
Ambulatory Subjects; Collection in the Morning	
Rise	1-3 hr before collection (record time)
Transport	Public or car transport for maximum of 45 min; walking a maximum of 500 m (≈ 550 yd) at moderate speed
Rest	Sitting for at least 15 min; arm muscle work not allowed
Collection	Between 0800 and 1000 hr (record time); sitting position with the arm approximately 45° below the horizontal position
Ambulatory Subjects; Collection in the Afternoon	
Breakfast	A light meal in the morning (approximately 310 kcal, 1300 kJ) composed of milk, coffee, or tea (maximum two cups); two open sandwiches with butter, slices of lunch meat/cheese, or marmalade
Activity	No exercise or heavy work
Rest	Sitting at least 15 min; arm muscle work not allowed
Collection	Between 1300 and 1500 hr (record time); minimum of 4 hr after breakfast; otherwise as above
Collection and Handling of Specimen*	
Venipuncture	In the cubital fold; no tourniquet; finger pressure proximal to the site allowed
Difficulties	A new attempt on opposite arm after 15 min rest

Based on Scandinavian recommendations.[4,21]

*Consult Chapter 2 for a discussion of other requirements for the collection and handling of specimens.

for routine clinical use of reference values. The interpretation is simplest if a patient's values and reference values are comparable with regard to analytical imprecision. For the same reason, it is advisable to analyze specimens from reference individuals in several runs to include the between-run components of variation. A safe way to obtain comparability is to include these specimens in routine runs together with the patient's specimens.

STATISTICAL TREATMENT OF REFERENCE VALUES

This section deals with two main topics: the partitioning of reference values into more homogeneous classes and the determination of reference limits and intervals. The subject matter is presented in the order in which data often are treated. Figure 16-2 gives an outline and refers to the corresponding sections in the text. Before the presentation of the methods, some statistical concepts used are briefly discussed (see also Chapter 14). A textbook by Harris and Boyd gives an excellent survey of the statistical bases of reference values in laboratory medicine.[27]

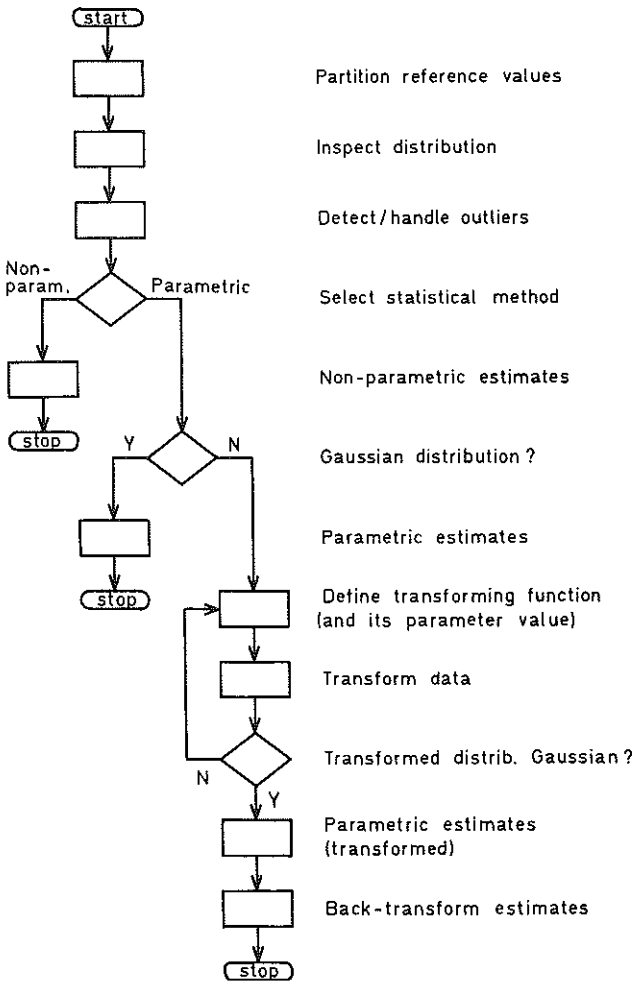

Figure 16-2 The statistical treatment of reference values. The "boxes" in the flow chart refer to sections in the text. NB = Nota bene: The order of the three first actions (partitioning, inspection, and detection and/or handling of outliers) may vary, dependent on the distribution and the statistical methods applied. *Y*, Yes; *N*, no.

STATISTICAL CONCEPTS

The first step in the establishment of reference values is the selection of a group of reference individuals. It is usually not feasible to obtain observations on all possible reference individuals of a certain category of the general population. We therefore hope that the smaller group examined, the *subset* (sometimes called the reference *sample* group), can give us the desired information about the characteristics of the complete *set* of individuals (the reference *population*).[34]

The larger set is often considered *hypothetical* because its characteristics are not observed directly; we know neither the number (the set size) nor the properties of all its individuals. We therefore want to infer from observations made on the subset to the hypothetical set. An obvious requirement is that the individuals in the subset are typical of those in the complete set. Statistical theory usually assumes that the items in the subset are selected at *random* from among those in the set; otherwise, the subset may be biased. If the items are not randomly selected, we can still use statistical techniques, but only with due caution and remembering the possible bias introduced.

There are two main types of *inferences* made from values obtained from the subset (sample group) to the set (total reference population).

1. We can **estimate properties** of the set. A reference limit (a percentile) of a biological quantity, such as the concentration of serum triglycerides, based on subset reference values, is an example of a *point estimate* (a single value). We consider it representative of the property that might have been found if we had observed all possible values in the set. If we examine many randomly selected subsets from the same set, we obtain several estimates with some variation around the "true" value of the set. It is possible to produce an *interval estimate* bounded by limits within which the "true" value is located with a specified confidence: the confidence interval. The *confidence* interval is expressed as a number in the interval 0 to 1, indicating the degree on the scale between "never" and "always." Our reference limit for serum triglycerides could thus be associated by a confidence interval showing its region of uncertainty.

   The "true" (unknown, hypothetical) value of a property of the set is often called a *parameter* and given a lower-case Greek letter symbol. For example, the standard deviation of the population is symbolized by the Greek sigma: σ_x. The corresponding property determined in the subset is named a *statistic* and symbolized by a lower-case Latin letter (e.g., s_x for the standard deviation of the subset).
2. Another inference is to **test hypotheses** regarding properties of the set. We might, for example, state the hypothesis that the distribution of values for serum triglyceride

concentrations is of the Gaussian type (the "null" hypothesis). If the deviations of the subset values from the Gaussian distribution are small, we could ascribe them to variation caused by chance alone. In that case, we should be permitted to use statistical methods based on the Gaussian distribution. However, we must reject the hypothesis if it is unlikely that the observed deviations from the Gaussian distribution are caused by chance alone. *Statistical tests* provide quantitative approaches to these types of decisions: the null hypothesis is rejected if the statistical test shows that the probability of the hypothesis being true is less than a stated *significance level.* The *probability* (p) is a number in the interval of 0 to 1, indicating the degree on the scale between "unlikely" and "certain." If we state a significance level of 0.05 when we test our Gaussian hypothesis for the distribution of serum triglyceride values, we should reject it if the probability obtained by the test is, for example, $p = 0.01$. Then we have to accept the alternative hypothesis that the distribution is nonGaussian. The *power* of a statistical test is the probability of rejection when the "null" hypothesis is false.

In the following sections, we use the term *reference distribution*[34] for the distribution of reference values (x). The two statistics *arithmetic mean* ($\bar{x}$) and *standard deviation* (s_x) are measures of its location and the dispersion of the values in it, respectively. They are defined as

$$\bar{x} = \frac{\sum x}{n}$$

$$s_x = \sqrt{\frac{\sum (x-\bar{x})^2}{n-1}} = \sqrt{\frac{\sum x^2 - \frac{(\sum x)^2}{n}}{n-1}}$$

where x is any of the n reference values in the subset (or a subclass of it). Standard deviations are commonly computed as shown in the second part of the preceding equation. The result may, however, be grossly inaccurate owing to rounding errors introduced by calculators and computers.[61]

The variable x in the preceding formulas denotes a quantity that varies. In our context, it signifies a reference value. If the variable by chance may take any one of a specified set of values, we use the term *variate* (i.e., a random variable). In this section, we consider distributions of single variates (i.e., *univariate* distributions). In a later section, we also discuss the joint distribution of two or more variates (*bivariate* or *multivariate* distributions).

An observed distribution may be presented as a table or graph (histogram) showing the number of observations in small intervals (Figure 16-3, *A*). The number of observations in an interval divided by the total number of observations in the distribution (its size) is an estimator of the probability of finding a value in the corresponding interval of the hypothetical *probability distribution* of the population (assuming random sampling). By consecutive summing of all these ratios, starting with the leftmost interval of the observed distribution, we get an estimate of the hypothetical *cumulative probability distribution* (Figure 16-3, *B*).

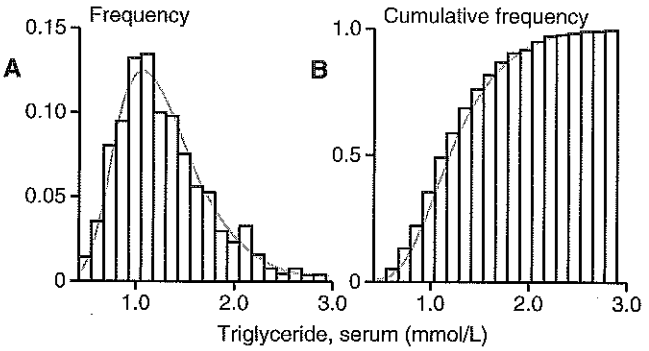

Figure 16-3 Observed and hypothetical distributions of 500 triglycerides values in serum (in mmol/L). **A,** The vertical bars of the left histogram show the number of observations in the interval divided by the total number of observations. The curve is the estimated probability distribution of the population, assuming random sampling and a log-Gaussian distribution. **B,** The cumulated ratios *(bars)* and the estimated cumulative probability distribution *(curve)*. (The data were computer generated for the purpose of illustration.)

Determination of Reference Limits: General Considerations

As mentioned previously, reference values provide a basis for interpretation of laboratory data. In clinical practice, one usually compares a patient's result with the corresponding *reference interval,* which is bounded by a pair of *reference limits.*[34] This interval, which may be defined in different ways, is a useful condensation of the information carried by the total set of reference values.

Three kinds of reference intervals have been suggested: tolerance interval, prediction interval, and interpercentile interval.[34,66] The choice from among these types of intervals may be important for certain well-defined statistical problems, but their numerical differences are negligible when based on at least 100 reference values.

The *interpercentile interval* is simple to estimate, more commonly used, and recommended by the IFCC.[34] This chapter, therefore, focuses on this type of interval. It is defined as an interval bounded by two percentiles of the reference distribution. A *percentile* denotes a value that divides the reference distribution such that a specified percentage of its values have magnitudes less than or equal to the limiting value. For example, if 2.32 mmol/L is the 97.5 percentile of serum triglycerides, 97.5% of the concentration values are equal to or below this value.

It is an arbitrary but common convention to define the reference interval as the *central 95% interval* bounded by the 2.5 and 97.5 percentiles (Figure 16-4) (i.e., 2.5% of the values are cut off in both tails of the reference distribution).[34]

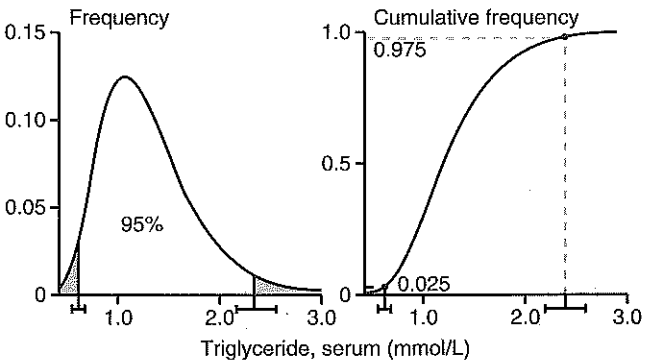

Figure 16-4 Central 95% reference interval. The 2.5 and 97.5 percentiles and their 0.90 confidence intervals of the 500 serum triglyceride concentrations (Figure 16-3), as determined by the parametric method (see text). The curves are the estimated probability distributions.

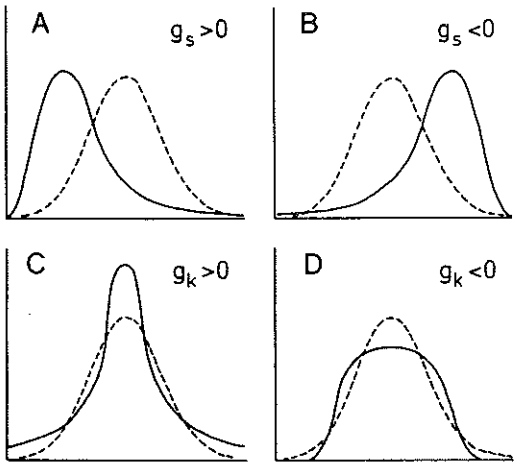

Figure 16-5 Skewness and kurtosis. The two upper figures show asymmetric distributions (**A,** positive skewness; **B,** negative skewness). The two lower figures show distributions with nonGaussian peakedness (**C,** positive kurtosis; **D,** negative kurtosis). The Gaussian distribution *(dashed curve)* is shown in all graphs for comparison. The values of the coefficients of skewness (g_s) and kurtosis (g_k) are also shown.

Another size or an asymmetrical location of the reference interval may be more appropriate in particular cases. To prevent ambiguity, the definition of the interval should always be stated. The estimation of percentiles presented in the following sections is based on the conventional central 95% interval, but the techniques are easily adapted to other locations of the limits.

The percentiles are point estimates of population parameters. Accordingly, they are unbiased estimates only if the subset of values was selected randomly from the population. But, as was discussed earlier, random sampling is often difficult to achieve. The interpercentile interval may always be used, however, as a summary or description of the subset reference distribution.

The precision of a percentile as an estimate of a population value depends on the size of the subset; it is less precise when there are few observations. If the assumption of random sampling is fulfilled, we may determine the *confidence interval* of the percentile (i.e., the limits within which the true percentile is located with a specified degree of confidence) (Figure 16-4). The 0.90 confidence interval of the 97.5 percentile (upper reference limit) for serum triglycerides may, for example, be 2.22 to 2.62 mmol/L. We would expect to find the true percentile in this interval with a confidence of 0.90 if we measured all serum triglyceride concentrations in the total reference population.

The interpercentile interval can be determined by parametric, nonparametric, and "bootstrap" statistical techniques.[27,34]

The *parametric method* for the determination of percentiles and their confidence intervals assumes a certain type of distribution, and it is based on estimates of population parameters, such as the mean and the standard deviation. We are, for example, using a parametric method if we believe that the true distribution is Gaussian and determine the reference limits (percentiles) as the values located 2 standard deviations below and above the mean. Most of the parametric methods are, in fact, based on the Gaussian distribution. If the reference distribution shows another shape, we may use mathematical functions that transform data to approximately Gaussian shape. Some positively skewed distributions (Figure 16-5, *A*) may, for example, be made symmetrical by using logarithms of the data values.

The *nonparametric method* makes no assumptions concerning the type of distribution and does not use estimates of distribution parameters. The percentiles may simply be determined by cutting off the required percentage of values in each tail of the subset reference distribution.

Originally a simple nonparametric method for determination of percentiles was recommended by the IFCC.[34] However, the newer "bootstrap" method[27,57] is currently the best method available for determination of reference limits. The more complex parametric method is seldom necessary, but it will also be presented here owing to its popularity and frequent misapplication. When we compare the results obtained by these methods, we usually find that the estimates of the percentiles are very similar. Detailed descriptions of these methods are given later in this chapter.

Commonly used statistical computer program packages[8,56,67] may aid in the estimation of reference limits, but these packages lack some of the techniques described here. The RefVal program,[65] however, implements these methods completely.

Sample Size

In general the theoretical lower limit of the sample size required for the estimation of the 100α and $100(1-\alpha)$ percentiles is equal to $1/\alpha$. Thus the estimation of the 2.5 percentile requires at least $1/0.025 = 40$ observations. The

precision of percentiles increases with an increasing number of observations, as shown by the narrowing of their confidence intervals. A sample size of at least 120 reference values has been recommended.[27,34] However, more values may be necessary if distributions are very skewed.[42]

A Note on Terminology

The terms "reference limits" and "clinical decision limits" should not be confused.[52,71] *Reference limits* are descriptive of the reference distribution: they tell us something about the observed variation of values in the selected subset of reference individuals. Comparison of new values with these limits thus only conveys information about similarity with the given reference values. In contrast, *clinical decision limits* provide optimum separation among clinical categories. The latter limits may be based on analysis of reference values from several groups of individuals (healthy persons and patients with relevant diseases) and can thus be used for the purpose of differential diagnosis.[21,52,68] Here are some examples of terms related to clinical decision limits: diagnostic criterion, prognostic limit, therapeutic value, and toxicity threshold.

The term "reference range" is sometimes used for the IFCC-recommended term "reference interval," but this use should be discouraged because the statistical term *range* denotes the difference (a single value!) between the maximum and minimum values in a distribution.[37]

Partitioning of Reference Values

The best order of the first three actions outlined in Figure 16-2 (partitioning of reference values, inspection of the distribution, and detection and/or elimination of outliers) may in some cases be different from that shown in the figure. For example, it might be more appropriate to eliminate outliers before testing for partitioning. No strict rules for the order of these actions can be given as it depends on data and the statistical methods applied. With this caution in mind, the presentation in this chapter follows Figure 16-2.

The subset of reference individuals and the corresponding reference values may be partitioned according to gender, age, and other characteristics (Box 16-2). The process of partitioning is also called stratification, categorization, or subgrouping, and its results are called partitions, strata, categories, classes, or subgroups. In this chapter, we use the pair of terms *partitioning* (for the process) and *(sub)classes* (for its result).

The aim of partitioning is to provide a better basis for comparison of clinical laboratory results: *class-specific* reference intervals (e.g., age- and gender-specific reference intervals).

Various statistical criteria for partitioning have been suggested.[27,39] For example, an intuitive criterion states that partitioning is necessary if differences between classes are statistically significant (rejection of the "null" hypothesis of equal distributions). The distribution of reference values in the classes may show different locations (mean values vary) or different intraclass variations (standard deviations vary). These differences may be tested by statistical methods, which are not described here. The reader is referred to Chapter 14 and to standard textbooks of parametric[55,59] and nonparametric statistics.[11]

The differences of location or variation, however, may be statistically significant and still too small to justify replacing a single total reference interval with several class-specific intervals. Alternately, statistically nonsignificant differences can lead to situations in which the proportions of each subclass above the upper or below the lower reference limits (without partitioning) are much different from the desired 2.5% on each side. Harris and Boyd[27] therefore suggested criteria based on the ratio between the subclass standard deviations, a normal deviate test of means, and calculation of critical decision values dependent on the sample size.

Lahti and co-workers[39,40] focused on distances between reference limits instead of distances between means, and suggested new distance and proportion criteria for partitioning. Their model also makes it possible to account for unequal subclass prevalences and is applicable to distributions of various types.

Partitioning requires large samples of reference values. If not, the subclass sizes may be too small for reliable estimates of reference intervals.

To solve the subclass size problem, it has been suggested to estimate regression-based reference intervals. Instead of dividing, for example, the total material into several age classes, one may construct continuous age-dependent reference limits and their confidence regions. Simulation studies have shown that this method produces reliable estimates with small sample sizes.[75]

When the intended purpose of the reference interval is to detect individual changes in biochemical status, subject-based reference values may be more appropriate for interpretation than class-specific reference intervals.[24,25,27] We shall return to this problem at the end of this chapter.

In the following sections, we assume that we have a homogeneous reference distribution, either the complete distribution (if partitioning has been shown to be unnecessary) or a subclass distribution (after partitioning).

Inspection of Distribution

It is always advisable to display the reference distribution graphically and to inspect it. A *histogram,* as shown in Figure 16-3, *A,* is easily prepared and is the data display best suited for visual inspection. The examination of the histogram is a safeguard against the misapplication or misinterpretation of statistical methods, and it may give valuable information about data. We should look for the following characteristics of the distribution:

1. Highly deviating values *(outliers)* may represent erroneous values.
2. *Bimodal* or *polymodal* distributions have more than one peak and may indicate that the distribution is nonhomogeneous because of the mixing of two or more distributions. If so, the criteria used to select

reference individuals should be reevaluated, or partitioning of the values according to age, gender, or other relevant factors should be attempted.

3. The shape of the distribution should be noticed. It may be asymmetrical or more or less peaked than the symmetrical and bell-shaped Gaussian distribution (Figure 16-5). The asymmetry most frequently observed with clinical chemistry data is positive *skewness* (Figure 16-5, *A*). A symmetrical distribution with positive *kurtosis* has a high and slim peak and more values in both tails than the Gaussian type of distribution (Figure 16-5, *C*). Conversely, negative kurtosis indicates that the distribution has a broad and flat top with relatively few observations in the tails (Figure 16-5, *D*). Asymmetry and nonGaussian peakedness may be combined.
4. The visual inspection may also provide initial estimates of the location of reference limits that are useful as checks on the validity of computations.

Identification and Handling of Erroneous Values

An *erroneous value* can be traced to a gross deviation from the prescribed procedure for establishment of reference values.[26] Such values may either deviate significantly from the proper reference values (*outliers*) or be hidden in the reference distribution. Only a strict experimental protocol, with adequate controls at each step, can eliminate the latter type of erroneous values.

Visual inspection of a histogram is a reliable method for identification of possible outliers. It is important to keep in mind, however, that values far out in the long tail of a skewed distribution may easily be misinterpreted as outliers. If the distribution is positively skewed, inspection of a histogram displaying the logarithms of the values may aid in the visual identification of outliers.

Some outliers may also be identified by *statistical tests* (see Chapter 14), but no single method is capable of detecting outliers in every situation that may occur. The number of techniques suggested or recommended is, for that reason, very large.[6,27,30] The two main problems encountered are as follows:

1. Many of the tests assume that the type of the true distribution is known before use of the test. Some of these specifically require that the distribution be Gaussian. However, biological distributions are very often nonGaussian, and their types are seldom known in advance. Furthermore, statistical tests of types of distribution are unreliable in the presence of outliers. We then have a difficult dilemma: some tests for outliers assume that the type of distribution is known, but tests for determining the type of distribution require that outliers be absent! As a consequence, it may be difficult to transform the distribution to Gaussian form before the identification of outliers by statistical tests. Some tests are relatively insensitive to departures from Gaussianity. This is the case with Dixon's *range test:* identify the extreme value as an outlier if the difference between the two highest (or lowest) values in the distribution exceeds one third of the range of all values.[27,34,53]
2. Several tests for outliers assume that data contain only a single outlier. The limitation of these tests is obvious. Some tests may detect a specified number of outliers, or they may be run several times, discarding one outlier in each pass of data. The range test, however, usually fails in the presence of several outliers. It is possible to estimate the standard deviation using data remaining after *trimming* of both tails of the distribution by a specified percentage of observations.[27,31] Outliers could be identified by this method as the values lying 3 or 4 standard deviations from the arithmetic mean. The method assumes, however, that the true distribution is Gaussian.

Horn and co-workers[33] have published a novel method in two stages for outlier detection that seems to provide a promising solution to both of the problems mentioned above.

1. Mathematically transform the data to approximate a Gaussian distribution. Horn et al used the Box-Cox transformation,[9] but other transformations that correct for skewness (see below) would probably also work. As mentioned above, it is impossible to achieve exact symmetry by transformation in the presence of outliers, but this does not seem to be critical with Horn's method.
2. Identify (or eliminate) outliers by a criterion based on the central 50% of the distribution, thus reducing the masking effect of several outliers. Compute the interquartile range (*IQR*) between the lower and upper quartiles of the distribution (Q_1 and Q_3, respectively): $IQR = Q_3 - Q_1$. Then identify as outliers data lying outside the two fences $Q_1 - 1.5*IQR$ and $Q_3 + 1.5*IQR$.

Deviating values identified as possible outliers cannot always be discarded automatically. Values should be included or excluded on a rational basis. Check the records of the dubious values and correct errors. In some cases, deviating values should be rejected because noncorrectable causes have been found, such as previously unrecognized conditions, qualifying individuals for exclusion from the group of reference individuals.

Methods for Determining Reference Values

Nonparametric, parametric, and bootstrap methods are used to determine reference intervals.

Nonparametric Method

This method consists essentially of cutting off a specified percentage of the values from each tail of the reference distribution. Three techniques may be used:

1. The percentiles may be determined *graphically* by plotting the cumulative distribution on ordinary graph paper (Figure 16-4, *B*) or preferably on Gaussian probability paper.

TABLE 16-3 Nonparametric Confidence Intervals of Reference Limits*

	Rank Numbers			Rank Numbers	
Sample Size	Lower	Upper	Sample Size	Lower	Upper
119-132	1	7	566-574	8	22
133-160	1	8	575-598	9	22
161-187	1	9	599-624	9	23
188-189	2	9	625-631	10	23
190-218	2	10	632-665	10	24
219-248	2	11	666-674	10	25
249-249	2	12	675-698	11	25
250-279	3	12	699-724	11	26
280-307	3	13	725-732	12	26
308-309	4	13	733-765	12	27
310-340	4	14	766-773	12	28
341-363	4	15	774-799	13	28
364-372	5	15	800-822	13	29
373-403	5	16	823-833	14	29
404-417	5	17	834-867	14	30
418-435	6	17	868-871	14	31
436-468	6	18	872-901	15	31
469-470	6	19	902-919	15	32
471-500	7	19	920-935	16	32
501-522	7	20	936-967	16	33
523-533	8	20	968-970	17	33
534-565	8	21	971-1000	17	34

*The table shows the rank numbers of the 0.90 confidence interval of the 2.5 percentile for samples with 119 to 1000 values. To obtain the corresponding rank numbers of the 97.5 percentile, subtract the rank numbers in the table from $(n + 1)$ where n is the sample size.
From IFCC.[34]

2. A *mathematical function* may be fitted to the reference distribution.[27,54,57] The percentiles are then determined using the fitted function.
3. Very simple and reliable methods are based on *rank numbers.*[34,43,53] They also allow nonparametric estimation of the confidence intervals of the percentiles.[53] The method can easily be applied manually or with a spreadsheet program.

The rank-based method as recommended by the IFCC has the following steps:[34]

a. Sort the n reference values in ascending order of magnitude.
b. Rank the values. The minimum value has rank number 1, the next value has rank number 2, and so on until the maximum value, which has rank number n. Consecutive rank numbers should be given to two or more values that are equal ("ties").
c. Compute the rank number of the 100α and $100(1 - \alpha)$ percentiles as $\alpha(n + 1)$ and $(1 - \alpha)(n + 1)$, respectively. Thus the limits of the conventional 95% reference interval have rank numbers equal to $0.025(n + 1)$ and $0.975(n + 1)$.
d. Determine the percentiles by finding the original reference values that correspond to the computed rank numbers, provided that the rank numbers are integers. Otherwise, interpolate between the two limiting values.
e. Finally, determine the confidence interval of each percentile using the binomial distribution.[53] Table 16-3 facilitates this for the 0.90 confidence interval of the 2.5 and 97.5 percentiles. Just enter the table and look up the bounding rank numbers for each percentile.

Table 16-4 shows an example of the nonparametric determination of percentiles using the serum triglyceride values shown in Figure 16-3.

Parametric Method

The parametric method is much more complicated than the simple nonparametric method and requires computer software.[65] The method is presented here under separate headings for testing of type of distribution, transformation of data, and the estimation of percentiles and their confidence intervals.

TABLE 16-4 Nonparametric Determination of Reference Interval*

Sorted and Ranked Serum Triglyceride Values in the Left Tail of the Distribution:

Values:	0.41	0.43	0.45	0.46	0.47	0.49	0.51	0.55	0.55	0.55
Ranks:	1	2	3	4	5	6	7	8	9	10
Values:	0.56	0.58	0.58	0.61	0.62	0.62	0.64	0.64	0.65	0.65
Ranks:	11	12	13	14	15	16	17	18	19	20

Sorted and Ranked Triglyceride Values in the Right Tail of the Distribution:

Values:	2.21	2.22	2.26	2.27	2.27	2.28	2.30	2.31	2.34	2.35
Ranks:	481	482	483	484	485	486	487	488	489	490
Values:	2.48	2.50	2.55	2.62	2.63	2.65	2.72	2.78	2.90	2.91
Ranks:	491	492	493	494	495	496	497	498	499	500

Calculation of Rank Numbers of the Percentiles:

Lower: $0.025(500 + 1) = 12.5$
Upper: $0.975(500 + 1) = 488.5$

Finding the Original Values Corresponding to These Rank Numbers:

Lower reference limit (2.5 percentile): 0.58
Upper reference limit (97.5 percentile): 2.32 (by interpolation)

Rank Numbers and Values of the 0.90 Confidence Limit of the Lower Reference Limit:

Rank numbers (Table 16-3): 7 and 19
Confidence limits: 0.51 and 0.65

Rank Numbers and Values of the 0.90 Confidence Limit of the Upper Reference Limit:

Rank numbers (Table 16-3): $500 + 1 - 19 = 482$
$500 + 1 - 7 = 494$
Confidence limits: 2.22 and 2.62

Summary:

Lower reference limit: 0.58 [0.51-0.65] mmol/L
Upper reference limit: 2.32 [2.22-2.62] mmol/L

*The table shows an example using the 500 serum triglyceride concentrations displayed in Figure 16-3. See the text for a description of the nonparametric method. The unit of all concentrations in the table is mmol/L.

Testing Fit to Gaussian Distribution

The parametric method for estimating percentiles assumes that the true distribution is Gaussian. This fact was frequently ignored in the past and caused Elveback[15] to warn against "the ghost of Gauss." Negligence often results in seriously biased estimates of reference limits. If, for example, we compute the mean and standard deviation of the 500 serum triglyceride values displayed in Figure 16-3, and then calculate the reference interval as $\bar{x} \pm 1.960s_x$, we would find the following limits: 0.4 and 2.2 mmol/L (correct values: 0.6 and 2.3 mmol/L). A highly positively skewed distribution may even result in a negative value for the lower reference limit.

A critical phase in the parametric method is, therefore, to test the goodness-of-fit of the reference distribution to a hypothetical Gaussian distribution. If we must reject the Gaussian hypothesis at a specified significance level, we have two alternatives (Figure 16-2): either we can use the nonparametric method or we can try to apply mathematical transformation of data to approximate the Gaussian distribution. Only when the Gaussian hypothesis is not rejected by the test can we pass directly to parametric estimation of percentiles and their confidence intervals (Figure 16-2).

Goodness-of-fit tests have been reviewed by Mardia.[45] We shall discuss only a few simple tests[63,66] that have proved valuable for our purposes. One can broadly classify these tests into three groups: graphical procedures, coefficient-based tests, and tests that are based on shape differences between the observed and theoretical distributions.

1. *The graphical procedure* consists of plotting the cumulative distribution (Figure 16-3, *B*) on probability paper, which has a nonlinear vertical axis based on the Gaussian distribution. The plot should be close to a straight line if the distribution is Gaussian. It is, however, very diffi-

cult to evaluate visually the deviations from the straight line because of the nonlinearity of the vertical distances in the graph. For that reason, the use of the graphical method is not recommended.

2. *The coefficient-based tests* use statistical measures of skewness and kurtosis (Figure 16-5).[12,34,59,63,66] These measures are computed from the second, third, and fourth subset moments about the mean (m_2, m_3, and m_4, respectively):

$$m_k = \frac{\sum (x - \bar{x})^k}{n} \qquad (k = 2, 3, or\ 4)$$

The subset *coefficient of skewness*, g_s, and its asymptotic standard deviation, s_s (it approaches the true standard deviation as the number of observations increases), are computed by the following formulas:

$$g_s = \frac{m_3}{m_2 \cdot \sqrt{m_2}}$$

$$s_s = \sqrt{\frac{6}{n}}$$

The coefficient g_s is zero for the Gaussian and other symmetrical distributions. The sign of a nonzero coefficient indicates the type of skewness present in the data (Figure 16-5, *A* and *B*).

The subset *coefficient of kurtosis*, g_k, and its asymptotic standard deviation, s_k, are computed as follows:

$$g_k = \frac{m_4}{m_2^2} - 3$$

$$s_k = \sqrt{\frac{24}{n}} = 6 = 2 \cdot \sqrt{\frac{6}{n}}$$

The coefficient g_k is approximately zero for the Gaussian distribution. The sign of a nonzero coefficient indicates the type of kurtosis present in the data (Figure 16-5, *C* and *D*).

The statistical significance of these two coefficients may be found by referring to tables for testing skewness and kurtosis.[59] A rough test is obtained by dividing the coefficient by its standard deviation and then referring to a table of the Gaussian distribution. The latter procedure is only reasonably accurate for sample sizes above 1000 (for g_s) and 2000 (for g_k). Computer programs for calculation and testing of these coefficients are available.[8,29,56,65,67]

Example: The coefficients computed for the serum triglyceride data shown in Figure 16-3 are $g_s = 0.873$ and $g_k = 0.677$. Their critical values for $n = 500$ at the 0.02 level of significance are 0.255 and 0.60, respectively.[59] Both coefficients are thus statistically significant and the Gaussian hypothesis should be rejected (the data were, in fact, approximately log-Gaussian). We arrive at the same conclusion by the approximate tests using the ratio between a coefficient and its asymptotic standard deviation:

$$\frac{g_s}{s_s} = \frac{0.873}{\sqrt{\frac{6}{500}}} = 7.97$$

$$\frac{g_k}{s_k} = \frac{0.677}{\sqrt{\frac{24}{500}}} = 3.09$$

Both coefficients exceed 3 standard deviations. When using a computer program,[65] these probabilities were found: $p < 0.001$ for g_s and $p = 0.011$ for g_k.

3. Three *tests of shape differences* that can be used to evaluate goodness-of-fit are the Kolmogorov-Smirnov test, the Cramer-von Mises test, and the Anderson-Darling test.[34,45,63,66,69] Computer programs for all three tests are available.[65]

Here we focus only on the Anderson-Darling test, which has been recommended by the IFCC.[34] The procedure is as follows[34,63,66,69]:

a. Allow for rounding of data, for example, by adding random "noise":

$$x'_i = x_i + L(r_i - 0.5) \qquad (i = 1, \ldots, n)$$

Here x'_i is the value with random "noise" added, x_i is the original data value, L is the step size of the value scale (least significant digit (e.g., $L = 0.1$ if laboratory results are reported to one decimal place), and r_i is a random number between 0.0 and 1.0.

b. Sort the data values in an ascending order of magnitude.

c. Compute the deviations $v_i = (x'_i - \bar{x})/s_x$, where $\bar{x}$ is the mean and s_x is the standard deviation of the data values.

d. Now find the values w_i of the cumulative Gaussian distribution corresponding to the deviation v_i by using statistical tables or a computerized algorithm.

e. Calculate the test statistic A^2 by this formula:

$$A^2 = -n - \frac{\sum (2i - 1) \cdot [\ln(w_i) + \ln(1 - w_{n+1-i})]}{n}$$

f. Reject the hypothesis that the data distribution fits the Gaussian distribution at the 0.01 level of significance if the size-adjusted test statistic A^{2*} is greater than 1.092[69]:

$$A^{2*} = A^2 \cdot \left(1 + \frac{4}{n} - \frac{25}{n^2}\right)$$

Transformation of Data: Simple Method

In the previous section it was shown that $\sqrt{x} \pm 1.960 s_x$ of the serum triglyceride data in Figure 16-3 resulted in biased reference limits (too low values), as was to be expected with this positively skewed distribution. However, it is often possible to transform data mathematically to obtain a distribution of transformed values that approximates a Gaussian distribution. With these new values, the 2.5 and 97.5 percentiles are localized at 2 standard deviations on both sides of the

mean. The estimates may then be transformed back to the original measurement scale by using the inverse mathematical function.

It is frequently observed that *logarithmically transformed* values, $y = \ln(x)$, of a positively skewed distribution fit the Gaussian distribution rather closely. In other cases, *square roots* of the values, $\sqrt{x}$, result in a better approximation to the Gaussian distribution. This is the basis for the common use of the logarithmic and square root transformations when estimating reference limits. The method is applicable only to positively skewed distributions. The method is easily performed with a spreadsheet program. The procedure is as follows:

1. Test the fit of the distribution of original data to the Gaussian distribution. If the distribution has approximately Gaussian shape, the 2.5 and 97.5 percentiles can be calculated directly as $\bar{x} \pm 1.960 s_x$. Otherwise continue with the following steps.
2. Transform data by the logarithmic function $y = \ln(x)$ or by the square root function $y = \sqrt{x}$ and then test the fit to the Gaussian distribution. If the transformed distribution is significantly different from Gaussian shape, try another transformation or estimate the percentiles by the nonparametric method (see earlier in this chapter). Continue with the next step if the transformation to Gaussianity was successful.
3. Compute the mean y and the standard deviation s_y of transformed data. Then estimate the 2.5 and 97.5 percentiles in the transformed data scale as $\bar{y} \pm 1.960 s_y$.
4. The final step is reconversion of these percentiles to the original data scale. The inverse functions of the two transformations described here are:

   Inverse logarithmic function: $x = e^y = \exp(y)$
   Inverse square root function: $x = y^2$

It is also possible to estimate the confidence limits of percentiles determined by the parametric method. The method is presented in a later section.

Example: When using logarithms of the serum triglyceride values of Figure 16-3, we get a distribution very close to Gaussian shape. The mean and standard deviation of transformed data are $\bar{y} = 0.172$ and $s_y = 0.357$, respectively. The transformed 2.5 percentile is $0.172 - 1.960 \times 0.357 = -0.528$. On reconversion to the original data scale we get $\exp(-0.528) = 0.59$. The lower reference limit of serum triglycerides is thus 0.59 mmol/L. Similarly, we find that the upper reference limit is 2.39 mmol/L. These values are in close agreement with those found by the nonparametric method: 0.58 and 2.32 mmol/L (Table 16-4).

Transformation of Data: Two-Stage Method

Because the simple logarithmic and square root transformations often fail to produce the desired Gaussian shape of the distribution, Harris and DeMets[29] introduced the two-stage method: first use a function that transforms the distribution to symmetry (zero coefficient of skewness), and then apply another function that removes any remaining nonGaussian kurtosis. Several mathematical functions may serve the purpose,[27,66] but this chapter presents only the two-stage procedure recommended by the IFCC.[34] This method, which is based on exponential and modulus functions, is implemented in the RefVal computer program.[65] The successive approximations to symmetry and to Gaussian kurtosis (i.e., the iterative determination of the function parameters) are monitored by the coefficient-based tests, whereas the final evaluation has to be done by an independent test (e.g., the Anderson-Darling test; see earlier in this chapter).

The *exponential function* suggested by Manly[44] may correct for both positive or negative skewness:

$$y = \frac{\exp(\gamma \cdot x) - 1}{\gamma} \qquad (\gamma \neq 0)$$

$$y = x \qquad (\gamma = 0)$$

The *modulus function* of John and Draper[35] may remove any nonGaussian kurtosis from a symmetrical distribution:

$$z = sign\left[\frac{(|y|+1)^{\lambda} - 1}{\lambda}\right] \qquad (\lambda \neq 0)$$

$$z = sign[\ln(|y|+1)] \qquad (\lambda = 0)$$

The *sign* in the formulas above is the algebraic sign associated with each input value y.

Parametric Estimates of Percentiles and Their Confidence Intervals

General estimates for the 100α and $100(1-\alpha)$ percentiles and their 0.90 confidence intervals can be determined by the following method, provided that data (original or transformed) fit the Gaussian distribution[34]:

The 100α and $100(1-\alpha)$ percentiles are determined as

(mean) $\pm$ c (standard deviation)

where c is the $(1-\alpha)$ standard Gaussian deviate, as can be found in statistical tables. For the 2.5 and 97.5 percentiles, we must find the $(1 - 0.025) = 0.975$ standard Gaussian deviate: $c = 1.960$.

The 0.90 *confidence intervals* of these percentiles are estimated as[34,66]

$$\text{percentile} \pm 2.81 \cdot \frac{s_y}{\sqrt{n}}$$

where s_y is the standard deviation of the reference values (original or transformed) and n is the number of values. This formula is a special case of a general formula that can be used for confidence intervals of other sizes or for other percentiles.[34,66]

Example: The parametric estimate of the 2.5 percentile of serum triglycerides was determined previously by the logarithmic transformation. The 0.90 confidence limits of the lower percentile are then

$$-0.528 - 2.81 \cdot \frac{0.357}{\sqrt{500}} = -0.573 \qquad \exp(-0.573) = 0.56$$

$$-0.528 + 2.81 \cdot \frac{0.357}{\sqrt{500}} = -0.483 \qquad \exp(-0.483) = 0.62$$

Thus the complete estimate of the 2.5 percentile [and its 0.90 confidence interval] is 0.59 [0.56 – 0.62] mmol/L. The 97.5 percentile is, by the same method, found to be 2.39 [2.29 – 2.50] mmol/L.

Bootstrap Method

Bootstrap-based methods are reliable for estimating reference intervals.[27,43,57] The following version using the rank-based nonparametric method is simple and reliable:

1. Draw, with replacement, random samples of size n from the subset of n reference values. One draws "with replacement" if each value randomly selected from the subset is kept in the subset so that it may participate in the random selection of the next value. The number of resamples should be high (500 is a reasonable number of iterations).
2. For each resample, estimate the upper and lower reference limits (percentiles) by the rank-based nonparametric procedure described previously. Save the two estimates for each iteration.
3. Upon completion of all iterations, use the median of the resample estimates of each of the two reference limits as final estimates.
4. Then estimate the 0.90 confidence interval of each reference limit from the distribution of the percentile estimates.

Among available methods for estimation of reference limits and their confidence intervals, the bootstrap method probably is the most reliable one.[27,43] The location of estimated percentiles is always dependent on the characteristics of the particular subset of reference values. There are only two possible methods to provide percentile estimates that approach population values: using a very large sample or performing repeated sampling from the same parent population. Both methods are obviously expensive. The bootstrap method is a good alternative. Its advantages are: (1) it is economical because it is based upon resampling from a single subset of reference values; (2) it provides robust percentile estimates (with the mentioned single-sample limitation); and (3) the widths of the confidence intervals approach asymptotically those that would have been obtained by repeated sampling from the parent population.[13] A computer is necessary to run the large number of bootstrap iterations.[65]

The bootstrap version described here uses rank-based nonparametric percentile estimates. However, the bootstrap principle may be employed with any kind of estimation, parametric or nonparametric.

PRESENTATION OF AN OBSERVED VALUE IN RELATION TO REFERENCE VALUES

An observed value (patient's value) may be compared with reference values. This comparison is often similar to hypothesis testing, but it is seldom statistical testing in the strict sense. Ideally the patient and the reference individuals should match (i.e., we might state the hypothesis that they were all picked from the same set [population]). Often, however, this is not the case. Thus it is advisable to consider the reference values as the yardstick for a less formal assessment than hypothesis testing.

The clinician should always be supplied with as much information about the reference values as he or she needs for the interpretation. Reference intervals for all laboratory tests may be presented to the physicians in a booklet together with information about the analysis methods, their imprecision, and descriptions of the reference values. The aim must be to present to the physicians enough information for rational clinical judgments.

In addition, a convenient presentation of an observed value in relation to reference values may be a great help for the busy clinician.[14,21,34,62]

The presentation of the observed value together with a *listing of all the reference values* for the corresponding test is a feasible procedure only when few reference values are available. When we have many reference values, it is more convenient to present the *reference distribution* in a table, graphically in the form of a histogram (Figure 16-3, *A*), or by a plot of the cumulative distribution (Figures 16-3, *B* and 16-4, *B*). A very informative presentation of the observed value is to show its location on a graph. This is particularly suited for a computerized display.[21]

A more condensed technique is to present the observed value and the *reference interval* on the same report sheet. The reference intervals may be preprinted on report forms, or the computer system may select the appropriate age- and gender-specific reference interval from a file and print it next to the test result. This type of presentation can be graphical.[21]

It is also possible to compute various *mathematical indices* or to *flag* the results on reports using convenient symbols. When using such presentation methods, the original observed value should also be reported to allow comparison with results of other laboratory tests and metabolic calculations.

An observed value may be classified as "low," "usual," or "high" (three classes), depending on its *location in relation to the reference interval.* On reports, it is convenient to flag unusual results (e.g., by using "L" and "H" for "low" and "high," respectively).[21]

A more detailed division of the value scale has also been advocated.[14] The regions outside the reference interval may be subdivided to indicate how "unusual" the observed value is. The reference interval may also be subclassified. The advantages are doubtful, however, because the shape of the reference distribution is not taken into account.

Another popular method is to express the observed value by a *statistical distance measure.* Such distances are all ratios of the following type:

$$\frac{\text{observed value} - \text{measure of location}}{\text{measure of dispersion}}$$

The well-known *SD unit* or "normal equivalent deviate" is such a measure. It is calculated as the difference between the observed value and the mean of the reference values divided by their standard deviation.[23] Several similar ratios have been suggested,[16] but none has significant advantages over the other. All produce very confusing values if the reference distribution is very skewed. An observed value (e.g., with an SD unit of 2.2) would be above the 97.5 percentile if the reference distribution has a Gaussian shape, but might be well below the upper reference limit of a positively skewed distribution. Mathematical transformation of the reference distribution to the Gaussian shape may solve this problem.[62]

To report the observed value as a *percentile* of the reference distribution provides a very accurate measure of the relation.[14,54] The observed serum triglyceride value 2.4 mmol/L may, for example, be reported as 2.4 mmol/L (98th percentile). Alternatively, we can estimate the probability of finding a value closer to the mean than the observed value, the *index of atypicality*.[2,62]

When observed values of several analytes are reported simultaneously, it is possible to use multivariate analogs of the SD unit and the index of atypicality (see below).[1,2]

ADDITIONAL TOPICS

Transferability of Reference Values

The determination of reliable reference values for each test in the laboratory's repertoire is a major task and is often far beyond the capabilities of the individual laboratory. It would therefore be convenient if reference values generated in another laboratory could be used. This is especially important when ethical considerations limit the number of available individuals (e.g., when producing pediatric reference values). Then, cooperative establishment of reference values may be necessary.

A major prerequisite for transfer of reference values is that the populations be homogeneous (i.e., there should be no major ethnic, social, or environmental differences among them).

However, the problem of analytical transferability remains. The optimal, but usually very unrealistic, situation assumes that the analytical methods, including their calibration and quality assurance, are identical in the laboratories. A more pragmatic approach involves standardization of analytical protocols, common calibration, design of a sufficiently efficient external quality control scheme, and the use of mathematical transfer functions if the results still are not directly comparable.

The parameters of transfer functions may be estimated from the results obtained by analysis of a sufficient number of specimens (preferably human) spanning the relevant range of concentrations in all participating laboratories. Sometimes functions obtained by simple linear regression suffice: using $y = a_0 + a_1x$, the constant term a_0 compensates for systematic shifts among the methods, whereas the coefficient term a_1 adjusts for proportional differences. In other cases, a more elaborate system for transfer of laboratory data is necessary.[70] The mentioned transfer functions account only for analytical bias; however, adjustments for differences in imprecision may also be designed.

Multicenter production of reference values is gaining acceptance, both as a theoretical concept and as a practical approach. A Spanish study[18] introduced a cooperative model, simulating a virtual laboratory for 15 biochemical quantities. A recent project in the Nordic countries (NORIP[51,54a]) was aimed at the production of common reference intervals for 25 analytes.

The verification of transferred reference values or intervals is both important and problematic.[27] The comparison of a locally produced, small subset of values with the large set produced elsewhere using traditional statistical tests often is not appropriate because the underlying statistical assumptions are not fulfilled and because of the unbalanced sample sizes. Alternative methods using nonparametric tests[74] or Monte Carlo sampling[32] have been described.

Multivariate, Population-Based Reference Regions

The topic of the previous sections of this chapter has been univariate population-based reference values and quantities derived from them. Such values do not, however, fit the common clinical situation in which observed values of several different laboratory tests are available for interpretation and decision making. For example, the average number of individual clinical chemistry tests requested on one specimen received in the author's laboratory is 9.7. There are two models for interpretation by comparison in this situation. We can compare each observed value with the corresponding reference values or interval (i.e., we perform *multiple, univariate comparisons*); or we can consider the set of observed values as a single multivariate observation and interpret it as such by a *multivariate comparison*. In this section, the relative merits of these two approaches are discussed, and methods for the latter type of comparison are presented.

The Multivariate Concept

A univariate observation, such as a single laboratory result, may be represented graphically as a point on a line, the axis. The results obtained by two different laboratory tests performed on the same specimen (a bivariate observation) may be displayed as a point in a plane defined by two perpendicular axes. With three results, we have a trivariate observation and a point in a space defined by three perpendicular axes, and so on. We lose the possibility for visualization of a multivariate observation when there are more than three dimensions. Still, we can consider the multivariate observation as a point in a multidimensional hyperspace with as many mutually perpendicular axes as there are results of different tests. The prefix "hyper" signifies, in this context, "more than three dimensions." Such multivariate observations are also

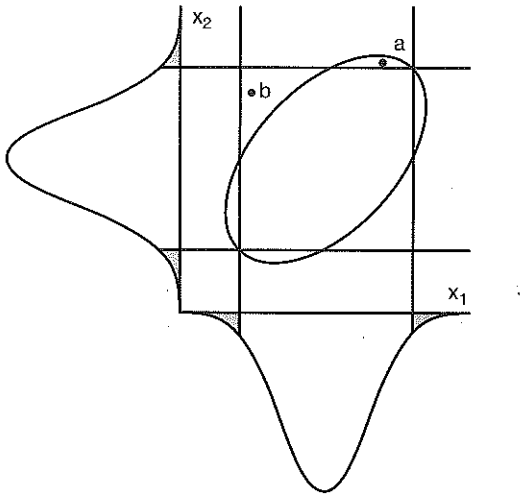

Figure 16-6 Bivariate reference region (*ellipse*) compared with the region defined by the two univariate reference intervals (*box*).

called *patterns* or *profiles*. A multivariate distribution is thus represented by a cluster of points on a plane, in a space, or in a hyperspace, depending on the dimensionality of the observation.[1,60,76] Several statistical methods are based on multivariate methods, and some of them are straightforward extensions of well-known univariate methods.[47]

The Multiple, Univariate Reference Region

The univariate reference interval is bounded by two reference limits on the result axis (Figure 16-4). Figure 16-6 shows that the univariate reference intervals for two laboratory tests describe a square in the plane of the two axes. Similarly, three or more univariate reference intervals define boxes or hyperboxes in the (hyper)space. By multiple, univariate comparison it can be decided whether a multivariate observation point lies inside or outside this square, box, or hyperbox. This method has, however, two very serious deficiencies[78]: an observation may lie outside the limits of the region without being unusual (Figure 16-6, point *a*), or it may be found on the inside and still be a very atypical observation (Figure 16-6, point *b*). If we use the central 95% interval, 5% of the values are by definition expected to be located in the two tails of the univariate reference distribution. But more than 5% of the values would be located outside the square or (hyper)box created by several 95% intervals. To be accurate, $100(1-0.95^m)$ percent of multivariate reference values would be excluded by the method of multiple, univariate comparison (m being the number of different tests or the dimensionality). We would, for example, expect to find $100(1-0.95^{10}) = 40\%$ of "false positives" when using 10 laboratory tests. This discouraging result has been verified in several multiphasic screening programs. We therefore need a better method.

The Multivariate Reference Region

It is possible to define a common multivariate reference region* based on the joint distribution of the reference values for two or more laboratory tests. This multivariate region is not a right-angled area or hyperbox, but more like an ellipse in the plane (Figure 16-6) or an ellipsoid hyperbody in hyperspace. This region may be a straightforward extension of the univariate 95% interval to the multivariate situation; it may be set to enclose 95% of the central multivariate reference data points. In that case, we would expect to find only 5% "false positives."

The use of multivariate reference regions usually requires the assistance of a computer program, which takes a set of results obtained by several laboratory tests on the same clinical specimen and calculates an index. The interpretation of a multivariate observation in relation to reference values is then the task of comparing the index with a critical value estimated from the reference values. This, obviously, is much simpler than comparing each result with its proper reference interval.

The index is essentially a distance measure, *Mahalanobis' squared distance* (D^2), which expresses the multivariate distance between the observation point and the common mean of the reference values, taking into account the dispersion and correlation of the variables.[1,2,10,47,60] More interpretational guidance may be obtained from this distance by expressing it as a percentile analogous to the percentile presentation of univariate observed values.[10] Also, the index of atypicality has a multivariate counterpart.[1,2]

Mahalanobis' squared distance of an observation is the multivariate analog of the square of the SD unit (d^2) discussed earlier:

$$d^2 = \left(\frac{x-\bar{x}}{S_x}\right)^2 = (x-\bar{x})\cdot\left(s_x^2\right)^{-1}\cdot(x-\bar{x})$$

The second form of the formula above is given to show the analogy to Mahalanobis' distance, which is defined as follows:

$$D^2 = (\boldsymbol{x}-\bar{\boldsymbol{x}})'\boldsymbol{S}^{-1}(\boldsymbol{x}-\bar{\boldsymbol{x}})$$

where $(\boldsymbol{x}-\bar{\boldsymbol{x}})'$ and $(\boldsymbol{x}-\bar{\boldsymbol{x}})$ are row and column vectors of the differences between each variable and its mean, and $\boldsymbol{S}^{-1}$ is the inverse matrix of variances and covariances. (According to the notation of matrix algebra, a lower-case boldface letter denotes a vector [an array of numbers]; the symbol for a matrix [a table of numbers] is a boldface capital letter.) The diagonal elements of the matrix $\boldsymbol{S}$ before inversion are the variances of the measures of the dispersion of individual variables. The covariances are measures of their interrelationship (off-diagonal elements of $\boldsymbol{S}$). The D^2 for a set of m-dimensional observations follows approximately a χ^2 distribution with m degrees of freedom. The critical value of D^2 for a 95% reference region is thus approximately the (1 –

*References 1, 2, 10, 27, 76, 78.

0.95) fractile of this distribution.[1,2,10] An observed pattern is located outside the multivariate region if its D^2 exceeds the critical value. If we want to report the D^2 as a percentile, we also refer to the same χ^2 distribution.[10]

Although the theory of multivariate reference regions has been known for a long time, surprisingly few applications of it have been reported in the literature. An important report reviews the topic and presents the results of a very careful study on the multivariate 95% region for a 20-test chemistry profile.[10] Some of the findings can be summarized as follows:

1. Sixty-eight percent of the subjects had at least one test result outside univariate reference intervals, which was close to what was theoretically expected: $100(1 - 0.95^{20}) = 64\%$.
2. By contrast, only 5% of the patterns were outside the multivariate reference region (as expected).
3. Transformation to approximately Gaussian shape of the univariate distributions was necessary.
4. A test profile may be distinctly unusual in the multivariate sense even though each individual result is within its proper reference interval (e.g., point B in Figure 16-6).
5. The multivariate reference region could detect minor deviations of multiple analytes.
6. Conversely, it could also be quite insensitive to highly deviating results for a single analyte.
7. The sensitivity could be increased by defining multivariate reference regions for subsets of physiologically related tests.

Subject-Based Reference Values

Figure 16-7 depicts the inherent problem associated with population-based reference values. It shows two hypothetical reference distributions. The one represents the common reference distribution based on single specimens obtained from a group of different reference individuals. It has a true (hypothetical) mean μ and a standard deviation σ. The other distribution is based on several specimens collected over time in a single individual, the *i*th individual. Its hypothetical mean is μ_i and the standard deviation σ_i.

If an observed value is located outside the subject's 2.5 and 97.5 percentiles, the personal or *subject-based reference interval,* the cause may be a change in the biochemical status, suggesting the presence of disease. Figure 16-7 shows that such an observed value may still be within the population-based reference interval. The sensitivity of the latter interval to changes in a subject's biochemical status depends accordingly on the location of the individual's mean μ_i relative to the common mean μ and to the relative magnitudes of the corresponding standard deviations σ_i and σ. A mean μ_i close to μ and a small σ_i relative to σ may conceal the individual's changes entirely within the population-based reference interval.

Harris[24,25] analyzed this topic and found that the ratio R of intraindividual (personal) variation over interindividual (among subjects) variation provides a criterion of the usefulness of the population-based reference interval. The population-based reference interval has less than the desired sensitivity to changes in biochemical status if the ratio value is $R \geq 0.6$. This interval is a more trustworthy reference if R is > 1.4, at least for the individual whose standard deviation σ_i is close to the average value. Published data[24,77] usually show that homeostatically tightly controlled quantities, such as serum electrolytes, have high ratio values. The population-based reference intervals of such analytes suffice for clinical use. For example, serum proteins and enzymes have very low ratios because they are not under the same degree of metabolic control. Here, subject-based reference intervals seem more appropriate.

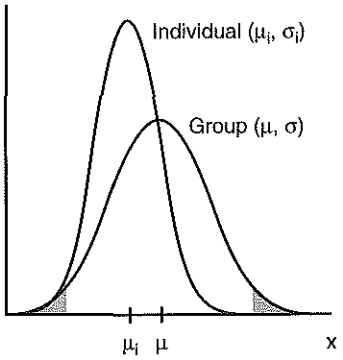

Figure 16-7 Relationship between population-based and subject-based reference distributions and reference intervals. The example is hypothetical, and the two distributions are, for simplicity, Gaussian. *(Modified from Harris EK: Effects of intraindividual and interindividual variation on the appropriate use of normal ranges. Clin Chem 1974; 20:1536.)*

There are two possible solutions to the problem of the clinical insensitivity of population-based reference intervals:

1. We can try to reduce the variation in the reference values by *partitioning* into more homogeneous subclasses, as was discussed in a previous section. But to increase the ratio R, for example, from 0.6 to 1.4 by partitioning, requires that we can obtain the rather dramatic reduction of 37% in the standard deviation.[24] This often is difficult to attain in practice.
2. The other possibility is to use the subject's previous values, obtained when the subject was in a well-defined state of health, as the reference for any future value. The application of *subject-based reference values* becomes more feasible as "health screening" by laboratory tests and as computer storage of results become available to large segments of the general population.

There are two not completely separated classes of models for construction of subject-based reference intervals: statistical and physiological models.[27]

1. Harris has developed several models based on statistical *time series analysis.*[24-28] At the one extreme, we have a stationary or *homeostatic model* suitable for analytes showing relatively fast, random fluctuations around a constant mean (set point). The set point is estimated from past values that are given equal weights. Another

model, the nonstationary *random-walk model,* allows a changing set point over time in healthy subjects. Then, the more recent values are given heavier weights during the estimation of the current set point. Intermediate and more or less complex models exist. Some of these data-following methods are suited for adaptive forecasting in situations in which the time intervals are short (e.g., during hospitalization).[26] They might thus be implemented on a computer as part of a laboratory cumulative reporting system. The reader is referred to papers by Harris for details on statistical time series models.[24-28]

2. It is also possible to construct *physiological models* that use known physiological and biochemical time-dependent relationships. Winkel has developed a time series model for monitoring plasma progesterone in pregnancy using the assumption of a simple exponential growth curve for the size of the placenta.[77]

Dynamic Versus Static Interpretation of Clinical Chemistry Data

The interpretation of observed values by comparison with population-based reference values or intervals is not the only way clinical data may be used. Often, dynamic approaches to data interpretation are more appropriate. Time-dependent variation may provide important information. The time series analysis of consecutive values from the same individual is one example. Other examples are the dynamic analysis of kinetic processes in the organism, such as intermediary metabolism and the exchange of substances between metabolic pools. For example, it is possible to design a model for urea turnover in the body.[19] The model defines the rates of urea input from various sources to the extracellular fluid, the exchange of urea across cell membranes, the urea degradation in the gut, the handling of urea by the kidneys, and so forth. Such a model may facilitate the interpretation of serum urea values with the purpose of detecting hemorrhage or necrosis after major surgery and the evaluation of the magnitude of these complications. Biochemical model building, estimation of model parameters from observed values, and computer simulation of the models may add greatly to our understanding.

CHAPTER 17

Preanalytical Variables and Biological Variation

Donald S. Young, M.B., Ph.D.,
and Edward W. Bermes, Jr., Ph.D.

The human body is composed of many different compounds and elements; the concentration or activities of these analytes are a reflection of the individual's health or pathophysiological state. However, both preanalytical variables and biological variation affect the concentration or activities of these analytes.[17,30,37]

PREANALYTICAL VARIABLES

Preanalytical variables fall under two categories—those that are controllable and those that are not. Those that can be controlled have short-lived effects. Duration of the other factors is much longer. Standardization of specimen collection practices minimizes the variables that cause changes in test values within one day or from one day to another and thereby reduces the difficulty in interpretation of values (see Chapter 2). However, in many healthcare facilities, standardization is not always possible. Thus one must understand the influences of both controllable and uncontrollable variables on the composition of body fluids.

CONTROLLABLE VARIABLES

Many of the preanalytical variables related to specimen collection that were discussed in Chapter 2 are examples of controllable variables. Others include physiological variables and those associated with diet, lifestyle, stimulants, drugs, herbal preparations, and recreational drug ingestion.

Physiological Variables

Physiological variables that are controllable that affect analytical results include posture, prolonged bed rest, exercise, physical training, circadian variation, and travel.

Posture

In an adult, a change from a lying to an upright position results in a reduction of an individual's blood volume of about 10% (~600 to 700 mL). Because only protein-free fluid passes through the capillaries to the tissue, this change in posture results in the reduction of the plasma volume of the blood and an increase (~8% to 10%) in the plasma protein concentration. Normally the decrease with the change from lying to standing is complete in 10 minutes. However, 30 minutes is required for such a change to occur when one goes from standing to lying.

The typical pressure at the arterial end of a capillary is 24 mm Hg (3.2 kPa) and at the venous end 10 mm Hg (1.3 kPa), although it varies with the distance of the capillary from the heart.[42] Transfer of fluid and solute across a capillary wall depends on a complex interaction of hydrostatic and osmotic pressures of the capillary and interstitial fluids. Fluid moves into the interstitial space at the arteriolar end of the capillary and returns to the capillary at the venular end. A greater volume of fluid leaves the capillary at the arteriolar end than is returned to the venous end. The excess drains into the lymphatic system. When an individual lies down, more fluid returns to the capillaries because the capillary pressure is reduced. The volume of fluid returning to capillaries progressively declines when an individual is recumbent for a long time. Diuresis serves as a mechanism to prevent overloading of the vascular system.

Heart rate and systolic and diastolic blood pressures are greater in the upright than in the recumbent individual. The change in posture from lying to standing increases the secretion of catecholamines, aldosterone, angiotensin II, renin, and antidiuretic hormone. Epinephrine and norepinephrine concentrations in plasma may double within 10 minutes, but

there is no change in their urinary excretion. The increase of plasma aldosterone and plasma renin activity is slower, but their concentrations may still double within 1 hour.

Substantial changes also take place with a change from the lying to the sitting position[45] or from standing to a supine or sitting position.[9] The reduction of the extracellular fluid volume with standing reduces the renal blood flow and causes a reduction of the glomerular filtration rate and urine production. The changes are apparent in 1 hour. Lithium, used therapeutically to treat some forms of schizophrenia, responds in the same way as sodium to postural changes. Sodium, potassium, and lithium excretions are reduced in response to increased hormone secretion, but the normal diurnal variation persists. When an individual stands, his urinary pH decreases and excretion of bicarbonate is reduced as hydrogen ions are exchanged for sodium. The excretion of protein is reduced in most individuals with the reduction of the glomerular filtration rate that occurs with standing. Orthostatic proteinuria is a condition in which protein is present when individuals are standing but essentially absent when they are recumbent. This phenomenon is possibly caused by increased glomerular permeability from increased venous pressure. The incidence of orthostatic proteinuria is probably less than 5%.

Normally the alteration of blood volume that takes place with a change from standing to lying is complete in 30 minutes. The decrease with the change from lying to standing is complete in 10 minutes. Changes in concentration of proteins and protein-bound constituents in serum are greater in hypertensive patients than normotensive patients, in individuals with a low plasma protein concentration than in those with a normal concentration, and in the elderly compared with the young. Most of the plasma oncotic pressure is attributable to albumin because of its high concentration, so that protein malnutrition—with its associated reduction of plasma albumin concentration—reduces the retention of the fluid within the capillaries. Conversely the impact of postural changes is less in individuals with abnormally high concentrations of protein, such as those with a monoclonal gammopathy (multiple myeloma).

In general, the concentrations of freely diffusible constituents with molecular weights of less than 5000 Da are unaffected by postural changes. However, a significant increase in potassium (~0.2 to 0.3 mmol/L) occurs after an individual stands for 30 minutes. This increase in K^+ has been attributed to the release of intracellular potassium from muscle. Although postural changes affect urinary sodium excretion, its plasma concentration is only slightly affected.

Changes in the concentration of some major serum constituents with change in posture are listed in Table 17-1.

TABLE 17-1 Change in Concentration of Serum Constituents With Change from Lying to Standing

Constituent	Average Increase (%)
Alanine aminotransferase	7
Albumin	9
Alkaline phosphatase	7
Amylase	6
Aspartate aminotransferase	5
Calcium	3
Cholesterol	7
IgA	7
IgG	7
IgM	5
Thyroxine	11
Triglycerides	6

From Felding P, Tryding N, Hyltoft Petersen P, et al. Effects of posture on concentrations of blood constituents in healthy adults: Practical application of blood specimen collection procedures recommended by the Scandinavian Committee on Reference Values. Scand J Clin Lab Invest 1980;40:615-21.

Prolonged Bed Rest

The plasma and extracellular fluid volumes decrease within a few days of the start of bed rest. Consequently the blood hematocrit may increase by as much as 10% within 4 days. There is usually a slight reduction of total body water.

With prolonged bed rest, fluid retention occurs and plasma protein and albumin concentrations may be decreased by an average of 0.5 and 0.3 g/dL, respectively. The concentrations of protein-bound constituents are also reduced, although mobilization of calcium from bones with an increased free ionized fraction compensates for the reduced protein-bound calcium, so serum total calcium is less affected. Serum aspartate aminotransferase activity is usually slightly less in individuals confined to bed than in those undertaking normal physical activity. Initially and paradoxically, creatine kinase (CK) activity is increased as a result of its release from skeletal muscles, but ultimately, CK activity may be less than in active, healthy individuals. Serum potassium may be reduced by up to 0.5 mmol/L because of reduction of skeletal muscle mass.

Prolonged bed rest is associated with increased urinary nitrogen excretion. Calcium, sodium, potassium, phosphate, and sulfate excretions are increased; hydrogen ion excretion is reduced, presumably caused by decreased metabolism of skeletal muscle.[13] The amplitude of circadian variation of plasma cortisol is reduced by prolonged immobilization, and the urinary excretion of catecholamines may be reduced to one third of the concentration in an active individual. Vanillylmandelic acid excretion is reduced by one fourth after 2 to 3 weeks of bed rest.

When an individual becomes active after a period of bed rest, more than 3 weeks are required before calcium excretion reverts to normal, and another 3 weeks before positive calcium balance is achieved. Several weeks are required before positive nitrogen balance is restored.

Exercise

In considering the effects of exercise the nature and extent of the exercise should be taken into account. Static or isometric exercise, usually of short duration but of high intensity, uses previously stored adenosine triphosphate (ATP) and creatine phosphate whereas more prolonged exercise must use ATP generated by the normal metabolic pathways. The changes in concentrations of analytes as a result of exercise are largely due to shifts of fluid between the intravascular and interstitial compartments, changes in hormone concentrations stimulated by the change in activity and by loss of fluid due to sweating. The physical fitness of an individual may also affect the extent of a change in the concentration of a constituent. Such factors account for the sometimes conflicting reports in the literature. Whether these effects are significant often depends on how long after an exercise activity a specimen was collected.

With *moderate exercise,* the provoked stress response causes an increase in the blood glucose, which stimulates insulin secretion. The arteriovenous difference in glucose concentration is increased by the greater tissue demand for glucose. Plasma pyruvate and lactate are increased by the increased metabolic activity of skeletal muscle. Even mild exercise may increase the plasma lactate twofold. Arterial pH and PCO_2 are reduced by exercise. Reduced renal blood flow causes a slight increase in the serum creatinine concentration. Competition between uric acid and lactate and products of increased tissue catabolism for renal excretion causes the serum urate concentration to increase. Exercise causes a reduction of cellular ATP, which increases cellular permeability. The increased permeability causes slight increases in the serum activities of enzymes originating from skeletal muscle, such as aspartate aminotransferase (AST), lactate dehydrogenase (LD), CK, and aldolase.[51] The increase of enzyme activity tends to be greater in unfit than fit individuals. As little as 5 minutes of walking increases the activity of these enzymes in plasma. Mild exercise produces a slight decrease in the serum cholesterol and triglyceride concentrations that may persist for several days. Those who walk for about 4 hours each week have an average cholesterol concentration 5% lower and high-density lipoprotein (HDL) concentration 3.4% higher than inactive individuals.

In general the effects of *strenuous exercise* are exaggerations of those occurring with mild exercise. Thus hypoglycemia and increased glucose tolerance may occur. The plasma lactate may be increased tenfold. Severe exercise increases the concentration of plasma proteins owing to an influx of protein from interstitial spaces, which occurs after an initial loss of both fluid and protein through the capillaries. The plasma concentrations of glycoproteins, transferrin, and α_2-macroglobulin are typically increased.[23] Fibrinolytic activity is also increased. Strenuous exercise may more than double CK activity, but the activity of enzymes with primarily liver or kidney origins is little changed, although both hepatic and renal blood flow are reduced.

Strenuous exercise for 10 minutes increases plasma renin activity by 400%. Cortisol secretion is stimulated and the normal diurnal variation may be abolished.[12] Urinary free cortisol excretion and the plasma concentrations of cortisol, aldosterone, growth hormone, somatotropin, and prolactin are also increased by exercise. Plasma insulin concentration is decreased by exercise. Strenuous exercise increases both the plasma and urinary concentrations of catecholamines. The changes in hormone concentrations are probably responsible for the increase in leukocyte count to about 25,000 cells/μL that has been observed following strenuous exercise.

The blood pH, oxygen saturation, and venous bicarbonate concentrations are decreased by strenuous exercise. The concentration of triglycerides is reduced briefly by exercise, but the free fatty acid concentration is greatly increased; serum creatinine and urea nitrogen concentrations are also increased. Although the creatinine concentration returns rapidly to normal on the cessation of exercise, the increased urea nitrogen concentration persists for some time. Reversible, benign hematuria and proteinuria occur commonly with exercise and worsen in proportion to the extent of the exercise. These may persist for 3 days following strenuous sports but do not warrant investigation.

Some representative changes in concentration or activity of serum constituents induced by exercise are listed in Table 17-2.

Physical Training

Athletes generally have a higher serum activity of enzymes of skeletal muscular origin at rest than do nonathletes. However, the response of these enzymes to exercise is less in athletes than in other individuals. The reduced release of enzymes from skeletal muscle in well-trained individuals has been attributed to an increase in the number and size of mitochondria allowing the muscle to better metabolize glucose, fatty acids, and ketone bodies. The proportion of CK that is CK-MB is much greater in the trained than untrained individual. Serum concentrations of urea, urate, creatinine, and thyroxine are higher in athletes than in comparable untrained individuals.[55] Urinary excretion of creatinine is also increased. These changes are probably related to the increased muscle mass and a greater turnover of muscle mass in athletes.

The total serum lipid concentration is reduced by physical conditioning; serum cholesterol may be lowered by as much as 25%. HDL cholesterol, however, is increased. Thus the decrease in total cholesterol concentration is mostly due to a reduction in low-density lipoprotein (LDL) cholesterol. The concentration of serum apolipoprotein A-1 increases with training, whereas the concentration of apolipoprotein B decreases. The serum triglyceride concentration may be reduced by up to 20 mg/dL (0.23 mmol/L), but the free fatty acid concentration is higher in fit individuals than others. Loss of body fat is associated with improvement in lipid concentrations. The lactate response to exercise is

TABLE 17-2 Effect of Strenuous Exercise on Selected Serum Constituents*

Constituent Value	% Increase	Constituent Value	% Decrease

From Statland BE, Winkel P, Bokelund H. Factors contributing to variation of serum constituents in healthy subjects. In: Siest G, ed. Organisation des laboratoires. Biologie perspective. Paris: L'Expansion Scientifique Francaise, 1975:717-50.
*Changes were determined 15 min after conclusion of 20 min exercise.

reduced in trained athletes compared with untrained individuals. In general the same exercise produces a less marked biochemical response in the fit person than in the unfit person.

Circadian Variation

Many constituents of body fluids exhibit cyclical variations throughout the day.[53] Factors contributing to such variations include posture, activity, food ingestion, stress, daylight or darkness, and sleep or wakefulness. These cyclical variations may be quite large, and therefore the drawing of the specimen must be strictly controlled. For example, the concentration of serum iron may change by as much as 50% from 0800 to 1400, and that of cortisol by a similar amount between 0800 and 1600. Serum potassium has been reported to decline from 5.4 mmol/L at 0800 to 4.3 mmol/L at 1400.[49] The typical total variation of several commonly measured serum constituents over 6 hours is illustrated in Table 17-3. The total variation is listed together with analytical error.

Hormones are secreted in bursts, and this, together with the cyclical variation to which most hormones are subject, may make it very difficult to interpret their serum concentration properly. Corticotropin secretion is influenced by cortisol-like steroids, but it is also affected by posture and by light, darkness, and stress. Its secretion is increased threefold to fivefold from its minimum between afternoon and midnight to its maximum around waking. Cortisol concentrations are greatest around 0600 to 0800 hours and may be twice as high as those observed at midnight.[52]

Maximum renin activity normally occurs early in the morning during sleep; its minimum occurs late in the afternoon. The plasma aldosterone concentration shows a similar pattern. Glomerular filtration rate (GFR) varies inversely with the secretion of renin. GFR is least at the time of maximum renin secretion and 20% greater in the afternoon when renin activity is at a minimum. The excretion of 17-ketosteroids and 17-hydroxycorticosteroids is low at night and reaches a maximum about midafternoon.

There is no circadian variation in the plasma concentrations of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in men, but a 20% to 40% increase of plasma testosterone occurs during the night. Prolactin is secreted, like other hormones, in multiple bursts; prolactin concentration is greatest during sleep.

The serum thyroid-stimulating hormone (TSH) is at a maximum between 0200 and 0400 and at a minimum between 1800 and 2200. The variation is of the order of 50%. There are also variations in the serum thyroxine concentration, but these appear to be related to the changes in concentration of binding protein brought about by changes in posture. These variations are maximal between 1000 and 1400. Total protein concentration may vary by as much as 10% over 24 hours, but the variation of individual proteins may be even greater.

Growth hormone secretion is greatest shortly after sleep commences. Conversely, basal plasma insulin is higher in the morning than later in the day, and its response to glucose is also greatest in the morning and least about midnight. When a glucose tolerance test is given in the afternoon, higher glucose values occur than when the test is given early in the day. The higher plasma glucose occurs in spite of a greater insulin response, which is nevertheless delayed and less effective.

Urinary excretion of catecholamines and their metabolites is less at night than during the day. The effect is related to activity, because in night workers excretion is less during the day.

The peak urinary excretion of sodium and potassium is about noon, whereas the excretion of calcium and magne-

TABLE 17-3 Total and Analytical Variation for Serum Tests on Specimens Obtained at 0800 and 1400*

Constituent	Mean	Total Variation (%)	Analytical Variation (%)
Sodium (mmol/L)	141	1.9	1.8
Potassium (mmol/L)	4.4	7.1	2.8
Calcium (mg/dL)	10.8	3.2	2.7

From Winkel P, Statland BE, Bokelund H. The effects of time of venipuncture on variation of serum constituents. Am J Clin Pathol 1975;64:433-47. Copyright 1975 by the American Society of Clinical Pathologists. Reprinted with permission.
*11 male subjects, age 21-27 years, studied at 0800, 1100, 1400.

sium is greatest during the night. Urinary phosphate excretion is low at night, with the result that serum phosphate is as much as 30% higher at night than during the morning. Urinary volume and creatinine excretion are low during the night. The creatinine clearance may be reduced by up to 10% during the night. Night urine contains excess ammonia and its titratable acidity is high.[50]

Travel

Travel across several time zones affects the normal circadian rhythm. Five days are required to establish a new stable diurnal rhythm after travel across 10 time zones. The changes in laboratory test results are attributable to altered pituitary and adrenal function. Urinary excretion of catecholamines is usually increased for 2 days; serum cortisol is reduced. During a flight, serum glucose and triglyceride concentrations increase, while glucocorticoid secretion is stimulated. During a prolonged flight, fluid and sodium retention occur, but urinary excretion returns to normal after 2 days.[8]

Space travel is associated with a decrease in blood and plasma volumes and is further associated with increases in plasma antidiuretic hormone, atrial natriuretic peptide, growth hormone, cortisol, and corticotropin concentrations. In contrast, the plasma renin activity may be decreased by as much as 50%. Plasma aldosterone may also decrease but to a lesser extent. In spite of the stress of space travel the plasma concentrations of catecholamines are usually unaffected. Plasma and urine calcium concentrations increase during space missions. Plasma sodium concentration decreases while its concentration in the urine increases.

Diet

Diet has considerable influence on the composition of plasma. Studies with synthetic diets have shown that day-to-day changes in the amount of protein are reflected within a few days in the composition of the plasma and in the excretion of end products of protein metabolism.

Four days after the change from a normal diet to a high-protein diet, a doubling of the plasma urea concentration occurs with an increase in its urinary excretion.[6] Serum cholesterol, phosphate, urate, and ammonia concentrations are also increased. A high-protein intake increases both serum and urinary urea and urate. A high-fat diet, in contrast, depletes the nitrogen pool because of the requirement for excretion of ammonium ions to maintain acid-base homeostasis. A high-fat diet increases the serum concentration of triglycerides but also reduces serum urate. Reduction of fat intake reduces serum lactate dehydrogenase activity. The ingestion of very different amounts of cholesterol has little effect on the serum cholesterol concentration; an increase in intake of 50% may only affect the serum concentration by 5 to 10 mg/dL (0.13 to 0.26 mmol/L).[32] Ingestion of monounsaturated fat instead of saturated fat reduces cholesterol and LDL cholesterol concentrations. When polyunsaturated fat is substituted for saturated fat the concentrations of triglycerides and HDL cholesterol are reduced.

When dietary carbohydrates consist mainly of starch or sucrose rather than other sugars, the serum activities of alkaline phosphatase (ALP) and LD are increased. AST activity is also influenced by the type of sugar ingested. The plasma triglyceride concentration is reduced when sucrose intake is decreased. Flatter glucose tolerance curves are observed with a bread diet than when a high-sucrose diet is ingested. A high-carbohydrate diet decreases the serum concentrations of very low-density lipoprotein (VLDL) cholesterol, triglycerides, cholesterol, and protein. Individuals who eat many small meals throughout the day tend to have concentrations of total LDL and HDL cholesterol concentrations that are lower than when the same type and amount of food is eaten in three meals.

In addition to the types of food and drinks ingested, specific food-related situations will also influence plasma composition. They include vegetarianism, obesity, malnutrition, fasting, and starvation.

Food Ingestion

The concentration of certain plasma constituents is affected by the ingestion of a meal, with the time between the ingestion of a meal and the collection of blood affecting the plasma concentrations of many analytes. For example, fasting overnight for 10 to 14 hours noticeably decreases the variability in the concentrations of many analytes and is seen as the optimal time for fasting around which to standardize blood collections. The biggest increases in serum concentrations occurring after a meal are for glucose, iron, total lipids, and ALP. The increase in ALP (mainly intestinal isoenzyme) is greater when a fatty meal is ingested and is influenced by the blood group of the individual and the substrate used for the enzyme assay. In addition, lipemia may affect some analytical methods used to measure serum constituents. Ultracentrifugation or the use of serum blanks can reduce the adverse analytical effects of lipemia.

The effects of a meal may be long lasting. Thus ingestion of a protein-rich meal in the evening may cause increases in the serum urea nitrogen, phosphorus, and urate concentrations that are still apparent 12 hours later. Nevertheless, these changes may be less than the typical intraindividual variability. Large protein meals at lunch or in the evening also increase the serum cholesterol and growth hormone concentrations for at least 1 hour after a meal. The effect of carbohydrate meals on blood composition is less than that of protein meals. No change in the cortisol concentration is noted when breakfast is taken, probably because cortisol completely occupies all cortisol binding sites on its binding protein in the early morning. Glucagon and insulin secretions are stimulated by a protein meal, and insulin is also stimulated by carbohydrate meals.

In response to a meal, the stomach secretes hydrochloric acid, causing a reduction in the plasma chloride concentration. The venous blood from the stomach contains an increased amount of bicarbonate. This condition reflects a mild metabolic alkalosis ("alkaline tide") and an increased PCO_2. The metabolic alkalosis is sufficient to reduce the serum-free ionized calcium by 0.2 mg/dL (0.05 mmol/L). After ingestion of a meal, the liver becomes the prime site for metabolism of the ingested substances. This metabolic activity may impair its secretory capability and thus accounts for the observed increase in postprandial bilirubin concentration, bromsulphalein (BSP) retention, and serum enzyme activity.

The effects of ingestion of a 700-kcal (2.93 MJ) meal on some commonly measured blood constituents are illustrated in Table 17-4. The effects differ with different meals. Thus glucose increase is often greater and phosphate usually decreases after a carbohydrate meal.

The ingestion of one glass of water has been observed to be followed by statistically significant alterations in the concentration of several of the commonly measured test constituents. When 75 g glucose is ingested with water, as in a glucose tolerance test, the concentration of glucose increases. This stimulates the secretion of insulin. Insulin causes the release of sodium from cells and stimulates the transport of potassium into the cells.

Ingestion of Specific Foods and Beverages

Constituents in food and drink will affect the composition of plasma. Bran, serotonin, and caffeine are examples of such constituents.

Bran. Habitual ingestion of bran impedes the absorption of certain compounds, including calcium, cholesterol, and triglycerides from the gastrointestinal tract. The concentration of calcium may be reduced by as much as 0.3 mg/dL (0.08 mmol/L) and that of triglycerides by 20 mg/dL (0.23 mmol/L), especially if triglycerides were high initially. Pectin and dietary fibers reduce the serum apolipoprotein B and cholesterol concentrations.

Serotonin. Many fruits and vegetables that contain 5-hydroxytryptamine (serotonin), such as bananas, cause an increased excretion of 5-hydroxyindoleacetic acid. Avocados impair glucose tolerance by affecting insulin secretion. Onions reduce both the plasma glucose and insulin response to glucose.

Caffeine. Caffeine is contained in many beverages, including coffee, tea, and colas and has considerable effect on the concentration of blood constituents. Caffeine stimulates the adrenal medulla, causing an increased excretion of the catecholamines and their metabolites and a slight increase in the plasma glucose concentration with impairment of glucose tolerance.[3] The adrenal cortex is also affected; plasma cortisol is increased, accompanied by increased excretion of free cortisol, 11-hydroxycorticoids, and 5-hydroxyindoleacetic acid. The effect of caffeine may be so great that the normal diurnal variation of plasma cortisol may be suppressed.

Caffeine has a marked effect on lipid metabolism. Ingestion of two cups of coffee may increase the plasma free fatty acid concentration by as much as 30% and glycerol, total

TABLE 17-4 Influence of a Standard 700-kcal Meal on Serum Constituents

Constituent	Before Meal	2 hr After Meal
Alanine aminotransferase (U/L)	31	33
Albumin (g/dL)	4.5	4.6
Alkaline phosphatase (U/L)	46	46
Aspartate aminotransferase (U/L)	22	28
Bilirubin (mg/dL)	0.7	0.8
Calcium (mg/dL)	9.9	10.0
Cholesterol (mg/dL)	220.0	220.0
Glucose (mg/dL)	71	82*
Lactate dehydrogenase (U/L)	198	198
Phosphate (mg/dL)	3.1	3.6*
Potassium (mmol/L)	3.8	4.0*
Sodium (mmol/L)	140	141
Total protein (g/dL)	7.8	7.9
Urea nitrogen (mg/dL)	16	16
Uric acid (mg/dL)	6.0	6.2

From Steinmetz J, Panek E, Sourieau F, et al. Influence of food intake on biological parameters. In: Siest G, ed. Reference values in human chemistry. Basel: Karger, 1973:193-200.

Results are mean values in 200 healthy individuals.

*Note also that other studies have reported greater increases in the glucose concentration and a reduction of the phosphate and potassium concentrations depending on the type of meal.

lipids, and lipoproteins to a lesser extent. Activation of triglyceride lipase causes the increase in nonesterified fatty acid concentration. Prolonged ingestion of caffeine (e.g., over several weeks) causes a slight reduction of the serum cholesterol concentration but an increase in the serum triglyceride concentration. No differences have been observed between the effects of caffeinated and decaffeinated coffee.

Caffeine is also a potent stimulant of gastric juice, hydrochloric acid, and pepsin secretion. The serum gastrin concentration may be increased by as much as five times after the ingestion of three cups of coffee. Coffee has a diuretic effect and also increases the excretion of erythrocytes and renal tubular cells in the urine. Caffeine increases the absolute amounts of sodium, potassium, calcium, and magnesium in urine—an effect not observed with decaffeinated coffee.

Vegetarianism

In long-standing vegetarians, the concentrations of LDL and VLDL cholesterol are reduced typically by 37% and 12%, respectively, compared with nonvegetarians. The total lipid and phospholipid concentrations are reduced, and the concentrations of cholesterol and triglycerides may be only two thirds of those in people on a mixed diet. Both HDL and LDL cholesterol concentrations are affected. In strict vegetarians the LDL concentration may be 37% less, and the HDL cholesterol concentration 12% less, than in nonvegetarians. The effects are less noted in individuals who have been on a vegetarian diet for only a short time. The lipid concentrations are also less in individuals who eat only a vegetable diet than in those who consume eggs and milk as well. When individuals previously on a mixed diet begin a vegetarian diet, their serum albumin concentration may fall by 10% and their urea concentration by 50%. However, there is little difference in the concentration of protein or of activities of enzymes in the serum of long-standing vegetarians and individuals on a mixed diet.

Urinary pH is usually higher in vegetarians than in meat eaters because of reduced intake of precursors of acid metabolites. The plasma vitamin B_{12} may be reduced in vegetarians to a concentration approaching that observed in deficiency. Vegetarians tend to have a higher serum bilirubin concentration than do meat eaters. An explanation for the low vitamin B_{12} and high bilirubin still has to be established. Differences in the composition of serum of vegetarians and nonvegetarians are listed in Table 17-5.

Malnutrition

In malnutrition, total serum protein, albumin, and β-globulin concentrations are reduced. The increased concentration of γ-globulin does not fully compensate for the decrease in other proteins. The concentrations of complement C3, retinol-binding globulin, transferrin, and prealbumin decrease rapidly with the onset of malnutrition[40] and are measured to define the severity of the condition. The plasma concentrations of lipoproteins are reduced, and serum cholesterol and triglycerides may be only 50% of the concentrations in healthy individuals. In spite of severe malnutrition, glucose concentration is maintained close to that in healthy

individuals. However, the concentrations of serum urea nitrogen and creatinine are greatly reduced as a result of decreased skeletal mass, and creatinine clearance is also decreased.

Plasma cortisol concentration is increased because of decreased metabolic clearance. The plasma concentrations of total triiodothyronine (T_3), thyroxine (T_4), and TSH are considerably reduced, with the thyroxine concentration being most affected. This is partly due to reduced concentrations of thyroxine-binding globulin and prealbumin.

Erythrocyte and plasma folate concentrations are reduced in protein-calorie malnutrition, but the serum vitamin B_{12} concentration is unaffected or may even be slightly increased.[33] The plasma concentrations of vitamins A and E are much reduced. Although the blood hemoglobin concentration is reduced, the serum iron concentration is initially little affected by malnutrition.

The activity of most of the commonly measured enzymes is reduced but increases with restoration of good nutrition.

Fasting and Starvation

Withdrawal of most, or all, caloric intake has been used to treat certain cases of obesity. Such withdrawal provokes many metabolic responses. The body attempts to conserve protein at the expense of other sources of energy, such as fat. The blood glucose concentration decreases by as much as 18 mg/dL (1 mmol/L) within the first 3 days of the start of a fast in spite of the body's attempts to maintain glucose production.[36] Insulin secretion is greatly reduced, whereas glucagon secretion may double in an attempt to maintain normal glucose concentration. Lipolysis and hepatic ketogenesis are stimulated. Ketoacids and fatty acids become the principal sources of energy for muscle. This results in an accumulation of organic acids that leads to a metabolic acidosis with reduction of the blood pH, PCO_2, and plasma bicarbonate concentrations. In addition, the concentrations of ketone bodies (acetoacetic acid and β-hydroxybutyric acid), fatty acids, and glycerol in serum rise considerably. Often the blood PO_2 is also reduced. Fasting for 6 days increases the plasma concentrations of cholesterol and triglycerides but causes a decrease in HDL concentration. With more prolonged fasting the concentrations of cholesterol and triglycerides decrease. Amino acids are released from skeletal muscle and the plasma concentration of the branched-chain amino acids may increase by as much as 100% with 1 day of fasting, but the urea concentration decreases.

The breakdown of fat leads to a transient increase in body water. Normally, however, an osmotic diuresis soon reduces the blood volume even though glomerular filtration may be impaired, as demonstrated by increased serum creatinine concentration and reduced creatinine clearance. Hepatic blood supply may also be reduced. BSP retention is increased, and the serum bilirubin rises; the unconjugated bilirubin more than doubles within 48 hours.[1] Increased serum activities of aspartate and alanine aminotransferase and of lactate dehydrogenase are observed. The enzyme changes may be linked more to focal necrosis of the liver than to general circulatory impairment.

In spite of the catabolism of tissue induced by starvation, the serum protein concentration is little affected initially; ultimately, a reduction occurs. However, from the beginning, the catabolism of nucleoproteins causes an increased serum urate. Rise in serum urate is exacerbated by the reduced GFR and the competition for excretion from lactate and ketoacids.

With the onset of starvation, aldosterone secretion increases with the results of increased urinary excretion and decreased plasma concentration of potassium. Magnesium, calcium, and phosphate are affected similarly, although the urinary excretion of phosphate gradually declines. The absolute urinary excretion of ammonia and creatinine increases with prolonged starvation but that of urea decreases.

Plasma growth hormone concentration may rise by as much as 15 times at the start of a fast but may return to normal after 3 days. Reduced energy expenditure is associated with decreased concentrations of thyroid hormones. Free and total triiodothyronine decrease by up to 50% within 3 days of the start of a fast. Free thyroxine concentration is also affected, but to a lesser extent; total thyroxine is little changed. Urinary free cortisol is decreased by fasting, and the plasma cortisol concentration (free and total) shows a slight increase together with loss of the normal diurnal variation.

Early in refeeding, sodium retention occurs as a result of decreased sodium and chloride excretion in the urine.[43] The

TABLE 17-5 Comparison of Blood Constituents between Vegetarians and Nonvegetarians

Constituent	Vegetarians	Nonvegetarians
S-Albumin (g/dL)	4.2	4.2
P-Calcium (mg/dL)	9.4	9.7
P-Cholesterol (mg/dL)	213	252
P-HDL cholesterol (mg/dL)	66	66
B-Glucose (mg/dL)	90	101
B-Hemoglobin (g/dL)	13.9	14.3
P-Triglycerides (mg/dL)	106	124

S, Serum; *P*, plasma; *B*, whole blood.

reduction in potassium excretion takes longer. These events are associated with an even greater secretion of aldosterone than occurs during the period of fasting. The abnormal concentrations of most constituents rapidly revert to normal with refeeding. Nitrogen balance soon becomes positive, especially if the nonprotein calories are mainly from carbohydrate.

Lifestyle

Lifestyle factors that affect the levels of commonly measured analytes include smoking and alcohol ingestion.

Smoking

Smoking, through the action of nicotine, may affect several laboratory tests. The extent of the effect is related to the number of cigarettes smoked and to the amount of smoke inhaled.

Through stimulation of the adrenal medulla, nicotine increases the concentration of epinephrine in the plasma and the urinary excretion of catecholamines and their metabolites.[10] Glucose concentration may be increased by 10 mg/dL (0.56 mmol/L) within 10 minutes of smoking a cigarette. The increase may persist for 1 hour. Plasma lactate is increased, and because the pyruvate concentration is reduced, the lactate-pyruvate ratio is increased. Plasma insulin concentration shows a delayed response to the increased blood glucose, rising about 1 hour after a cigarette is smoked. Typically the plasma glucose concentration is higher in smokers than in nonsmokers, and glucose tolerance is mildly impaired in smokers. The plasma growth hormone concentration is particularly sensitive to smoking. It may increase tenfold within 30 minutes after an individual has smoked a cigarette.

The plasma cholesterol, triglyceride, and LDL cholesterol concentrations are higher (by about 3%, 9.1%, and 1.7%, respectively), as is that of β-lipoprotein, and HDL cholesterol is lower in smokers than in nonsmokers. Free fatty acid concentration tends to be variable, but inhalation during smoking produces an immediate increase of free fatty acids of about 30%. Some of the effects of smoking on serum constituents are listed in Table 17-6.

TABLE 17-6 Reported Increased Concentrations in Serum in Smokers

Constituent	% Change
Albumin	3
Cholesterol	4
Glucose	10
Phospholipids	5
Triglycerides	20
Urea nitrogen	10

From Siest G, Henny J, Schiele F, (eds). Interpretation des examens de laboratoire. Basel: Karger, 1981.

Smoking affects both the adrenal cortex and the medulla; plasma 11-hydroxycorticosteroids may be increased by 75% with heavy smoking. In addition, the plasma cortisol concentration may increase by as much as 40% within 5 minutes of the start of smoking, although the normal diurnal rhythmicity of cortisol is unaffected. Smokers excrete more 5-hydroxyindoleacetic acid than do nonsmokers.

The blood erythrocyte count is increased in smokers. The amount of carboxyhemoglobin may exceed 10% of the total hemoglobin in heavy smokers, and the increased number of cells compensates for impaired ability of the red cells to transport oxygen. The blood PO_2 of the habitual smoker is usually about 5 mm Hg (0.7 kPa) less than in the nonsmoker, whereas the PCO_2 is unaffected. The blood leukocyte concentration is increased by as much as 30% in smokers, but the leukocyte concentration of ascorbic acid is greatly reduced. The lymphocyte count is increased as a proportion of the total leukocyte count.

Fluid retention caused by nicotine causes a mild decrease in the plasma protein concentration but without demonstrable effect on the calcium concentration or on the activity of serum enzymes. The plasma urate concentration is less in smokers than in nonsmokers, probably as a result of lessened intake of food by smokers. Both the serum urea and creatinine concentrations tend to be less in smokers than in nonsmokers.

Nicotine is a potent stimulant of the secretion of gastric juice. Both volume and acid secretion are increased within 1 hour of smoking several cigarettes. In contrast, the bicarbonate concentration and volume of pancreatic juice are reduced.

Smoking affects the body's immune response. For example, serum IgA, IgG, and IgM levels are generally lower in smokers than in nonsmokers, whereas the IgE concentration is higher. Smokers, more often than nonsmokers, may show the presence of antinuclear antibodies and test weakly positive for carcinoembryonic antigen. The sperm count of male smokers is often reduced compared with that in nonsmokers: the number of abnormal forms is greater and sperm motility is less.

The serum vitamin B_{12} concentration is often notably reduced in smokers, and the decrease is in inverse proportion to the serum concentration of thiocyanate.

Alcohol Ingestion

A single moderate dose of alcohol has few effects on laboratory tests. Ingestion of enough alcohol to produce mild inebriation may increase the blood glucose concentration by 20% to 50%. The increase may be even higher in diabetics. More commonly, inhibition of gluconeogenesis occurs and becomes apparent as hypoglycemia and ketonemia and ethanol is metabolized to acetaldehyde and to acetate. Hypoglycemia is most common in children, alcoholics, and the malnourished. Lactate accumulates and competes with urate for excretion in the kidneys so that the serum urate is also increased. Lactate and acetate together decrease the plasma

bicarbonate, leading to metabolic acidosis. Marked hypertriglyceridemia after alcohol ingestion is due to a combination of increased triglyceride formation in the liver and impaired removal of chylomicrons and VLDL from the circulation. The effect is most noticeable when alcohol is ingested with a fatty meal. The effect may persist for longer than 12 hours. When moderate amounts of alcohol are ingested for 1 week, the serum triglyceride concentration is increased by more than 20 mg/dL (0.23 mmol/L). Prolonged moderate ingestion of alcohol may increase the HDL cholesterol concentration, which is associated with reduced plasma concentration of cholesterol ester transfer protein (CETP). Phenols in wine with potent antioxidant activity are probably responsible for reducing the oxidation of LDL cholesterol.

Intoxicating amounts of alcohol stimulate the release of cortisol, although the effect is more related to the intoxication than to the alcohol per se. Sympatheticomedullary activity is increased by acute alcohol ingestion but without detectable effect on the plasma epinephrine concentration and only a mild effect on norepinephrine. With intoxication, plasma concentrations of catecholamines are substantially increased. Acute ingestion of alcohol leads to a sharp reduction in the plasma testosterone in men, with an increase in the plasma luteinizing hormone concentration.

Chronic alcohol ingestion affects the activity of many serum enzymes. Gamma-glutamyl transferase (GGT) activity has been extensively studied, and increased activity of the enzyme is used as a marker of persistent drinking. A single acute ingestion of alcohol has been reported to increase the serum activity of the enzyme, a manifestation of hepatic microsomal enzyme induction. Chronic alcoholism is associated with many characteristic biochemical abnormalities, including abnormal pituitary, adrenocortical, and medullary function. Acute alcohol ingestion has been reported to increase the activity of several serum enzymes, including GGT, isocitrate dehydrogenase, and ornithine carbamoyl transferase.[19,21] Alcohol ingestion also has considerable influence on serum HDL cholesterol and total cholesterol concentration.[58] Measurement of carbohydrate-deficient transferrin is becoming increasingly popular as a means of identifying habitual alcohol ingestion. Desialylation of proteins occurs because of inhibition of enzymatic glycosylation in the liver by alcohol. Increased mean cell volume (MCV) has also been used as a marker of habitual alcohol use and may be related to folic acid deficiency or a direct toxic effect of alcohol on red blood cell precursors.

Drug Administration

It is rare for a patient to be hospitalized without receiving medication. For certain medical conditions, more than 10 drugs may be administered at one time. Even many healthy individuals take several drugs regularly, such as vitamins, oral contraceptives, or sleeping tablets. Individuals with chronic diseases often ingest drugs on a continuing basis. Drugs may have both in vivo and in vitro effects on laboratory tests. The in vivo effects arise from the therapeutic intent of drugs, their side effects, and patient idiosyncrasies. Effects on the composition of body fluids are likely to be more apparent when large doses of a drug are administered for a long time than when administration of a single dose occurs on an isolated occasion.

Comprehensive listings of the effects of drugs on laboratory tests have been published.[56,57] Only a few representative effects are discussed here. Many drugs, when administered intramuscularly, cause sufficient muscle irritation to increase amounts of enzyme released into the serum. The activities of CK, aldolase, and the skeletal muscle component of lactate dehydrogenase are increased in the serum. The increased activities may persist for several days after a single injection, and consistently high values may be observed during a course of treatment. *Penicillin* derivatives given intramuscularly are particularly likely to increase the activity of these enzymes, although any drug given intramuscularly appears capable of increasing enzyme activity. Drugs that have been demonstrated to increase serum CK activity after intramuscular injection are listed in Table 17-7. *Opiates,* such as morphine or meperidine, can cause spasm of the sphincter of Oddi. The spasm transmits pressure back to the liver, causing release of liver and pancreatic enzymes into the serum. Increases in aspartate aminotransferase activity may be so large that they may be suggestive of a myocardial infarction.

Oral contraceptives affect many different constituents measured in the clinical laboratory. Tests are affected by both the progestin and estrogen components. The overall effect depends on the proportion and amount of the two components.

Diuretic drugs often cause a mild reduction of the plasma potassium concentration; hyponatremia may be observed. Hypercalcemia may occur with hemoconcentration, but occasionally the free-ionized and the protein-bound fraction is increased. Thiazides cause hyperglycemia and reduce glucose tolerance, especially in diabetics. Thiazides may cause prerenal azotemia with hyperuricemia as a result of decreased renal blood flow and GFR as a result of reduced blood volume. Thiazides, like other diuretics, by causing hemoconcentration increase the plasma concentration of lipids. Many thiazides induce microsomal enzymes and thus affect lipoprotein concentrations.

TABLE 17-7 Drugs Associated With Increased Serum Creatine Kinase Activity After Intramuscular Injection

Ampicillin	Chlorpromazine	Meperidine
Analgesics	Clindamycin	Morphine
Antibiotics	Digoxin	Penicillin
Barbiturates	Diuretics	Phenothiazines
Carbenicillin	Lidocaine	Tubocurarine

The broad range of possible effects of a drug on clinical laboratory tests is exemplified by *phenytoin*. With long-term treatment, many patients have reduced serum calcium and phosphate concentrations and increased activity of ALP. Phenytoin induces the synthesis of bilirubin-conjugating enzymes in the liver. Consequently the serum bilirubin concentration is reduced, serum GGT activity is increased, and urinary glucaric acid excretion is augmented. A few cases of increased serum aminotransferase activity have been reported, together with prolongation of the prothrombin time. Occasionally, cholestatic, cytotoxic, or mixed hepatic injury may occur. The overall incidence of slight alteration of liver function is about 25%.

Phenytoin decreases the urinary excretion of 17-ketosteroids and 17-hydroxycorticosteroids by stimulating the conversion of cortisol to 6-β-hydroxycortisol; it also diminishes serum FSH and the sperm count in semen, and thereby reduces fertility. Phenytoin also lowers the serum thyroxine concentration, probably by competitive displacement of thyroxine from its protein-binding sites; free thyroxine also tends to be low. Serum triiodothyronine is low, probably as a result of stimulated metabolism in the liver, but the concentration of TSH is unaffected by the altered thyroxine metabolism.

Many epileptics receiving anticonvulsants excrete increased amounts of copper and zinc in their urine. Increased serum ceruloplasmin also increases the total serum copper concentration. In 20% to 30% of epileptic children receiving anticonvulsant therapy, erythrocyte aspartate aminotransferase activity is low, indicating a lowered pyridoxal (vitamin B_6) status. In as many as 50% of the adults receiving phenytoin for some time, there will be folate deficiency, manifested by reduced erythrocyte and serum folate concentrations. The mechanism for the deficiency has not yet been established conclusively. In about 10% of adults taking phenytoin, the serum vitamin B_{12} is low.

T-cell function is reduced in many epileptics receiving anticonvulsants, and systemic lupus erythematosus occurs in about 10% of treated individuals. Antinuclear antibodies have been reported in 55%, and low serum IgA and IgG concentrations in 25% of the patients. Other reported biochemical abnormalities include reduced serum concentrations of HDL cholesterol, urate, and urea nitrogen.

Herbal Preparations

Herbal preparations vary greatly in effect and composition. Long-term use of aloe vera, sandalwood, and cascara segrada may cause hematuria and albuminuria. Through their laxative effects, prolonged use of aloe vera, Chinese rhubarb, frangula bark, senna, and buckthorn may lead to hypokalemia provoking hyperaldosteronism. Trailing arbutus may cause hemolytic anemia and liver damage. Green tea has been reported to cause microcytic anemia. Quinine and quinidine have been observed to cause thrombocytopenia. Cayenne *(Capsicum annuum)* increases fibrinolytic activity and induces hypocoagulability. Hyperthyroidism has been caused by bladderwrack. Many herbal preparations affect liver function. Germander has been reported to cause liver cell necrosis, and bishop's weed infrequently causes cholestatic jaundice. Tonka beans can cause reversible liver damage. Comfrey has been associated with one death from liver failure. Bugleweed reduces the plasma concentration of prolactin and reduces the deiodination of thyroxine.

Recreational Drug Ingestion

Amphetamines increase the concentration of free fatty acids. Morphine increases the activity of amylase and lipase, alanine and aspartate aminotransferases, ALP and the serum bilirubin concentration. The concentrations of gastrin, TSH, and prolactin are also increased. In contrast the concentrations of insulin, norepinephrine, pancreatic polypeptide, and neurotensin are decreased. Heroin increases the plasma concentrations of cholesterol, thyroxine, and potassium. PCO_2 is increased but PO_2 is decreased. The plasma albumin concentration is also decreased. Cannabis increases the plasma concentrations of sodium, potassium, urea, chloride, and insulin but decreases those of creatinine, glucose, and urate.

Noncontrollable Variables

Examples of noncontrollable preanalytical variables include those related to biological, environmental, and long-term cyclical influences and those related to underlying medical conditions.

Biological Influences

There is better agreement between the serum concentrations or activities of several constituents in monozygotic twins than in dizygotic twins.[31] This evidence indicates the importance of genetic constitution in determining the concentration of blood constituents. An influence of heredity has been substantiated on the plasma concentrations of cholesterol, glucose, urea nitrogen, urate, and bilirubin.

An association of blood type with concentration of certain constituents (uric acid, α_1-antitrypsin, cholesterol, and ALP) has been established. In women with blood group O, the blood hemoglobin concentration is generally less than in women with other blood groups. Histocompatibility antigens also have an underlying genetic basis but can be markedly influenced by prior blood transfusions.

The age, sex, and race of the patient influences the results of individual laboratory tests.[41,46] They are discussed individually in various chapters of this book, and reference intervals for various analytes as a function of these biological influences are listed in Chapter 56.

Age

Age has a notable effect on reference intervals; typical changes in serum composition occurring with age are listed

TABLE 17-8 Influence of Age on Mean Concentration of Serum Constituents in Males

	Measured Value	Change Compared With <29 Year Value			
	<29 y	30-39 y	40-49 y	50-59 y	60-69 y
Albumin (g/dL)	4.6	−0.2	−0.3	−0.4	−0.6
Alkaline phosphatase (U/L)	51	−3	−1	1	4
Aspartate aminotransferase (U/L)	41	3	3	1	1
Bilirubin (mg/dL)	0.4	0.1	0	0	0
Calcium (mg/dL)	9.8	−0.1	−0.2	−0.2	−0.3

Uric acid (mg/dL)	5.9	0	0.2	−0.1	−0.2

From Leonard PJ. The effect of age and sex on biochemical parameters in blood of healthy human subjects. In: Siest G, ed. Reference values in human chemistry. Basel: Karger, 1973:134-40.

in Table 17-8, although the degree of changes differs in various reports. In general, individuals are considered in four groups—the newborn, the older child to puberty, the sexually mature adult, and the elderly adult.

Newborn. The body fluids of the newborn infant reflect both the trauma of birth and the changes related to the infant's adaptation to an independent existence. The composition of the blood is affected by the maturity of the infant at birth. The erythrocyte count and the hemoglobin concentration in the neonate at birth are much higher than those of the adult but within a few days of birth erythrocytes degrade in response to the higher oxygen concentration than that to which the fetus was exposed in utero. In the mature infant, most of the hemoglobin is the adult form, hemoglobin A, whereas in the immature infant, much of the hemoglobin may be the fetal form, hemoglobin F. In both the mature and immature infant, the arterial blood oxygen saturation is very low initially. A metabolic acidosis develops in newborns that results from the accumulation of organic acids, especially lactic acid. The acid-base status, however, reverts to normal within 24 hours.

Within a few minutes of an infant's birth, fluid passes from the blood vessels into the extravascular spaces. This fluid is similar to plasma except that the fluid lost from the intravascular space contains no protein. Consequently the plasma protein concentration increases. The serum activities of several enzymes, including CK, GGT, and AST, are high at birth, but the increase of alanine aminotransferase (ALT) activity is less than that of other enzymes.

In infants, even in the absence of disease, the concentration of bilirubin rises after birth because of the enhanced erythrocyte destruction. Its concentration peaks about the third to fifth day of life. Conjugation of bilirubin is relatively poor in the neonate as a result of immature liver function. The physiological jaundice of the newborn rarely produces serum bilirubin values greater than 5 mg/dL (85 μmol/L). Distinguishing this naturally occurring phenomenon from other conditions that produce neonatal hyperbilirubinemia may be difficult, and the chronological course of the hyperbilirubinemia is important.

The blood glucose concentration is low in newborns because of their small glycogen reserves, although some attribute the low glucose to adrenal immaturity. Blood lipid concentrations are low but reach 80% of the adult values after 2 weeks. The plasma sodium concentration in an infant at birth is slightly higher than in the adult; at 12 hours, it decreases to below the adult value before rising to a value slightly greater than in the adult. The chloride concentration changes similarly, and the changes are largely related to fluid transfer in and out of the blood capillaries. The plasma potassium concentration may be as high as 7 mmol/L at birth, but it falls rapidly thereafter. Plasma calcium is also high initially but falls by as much as 1.4 mg/dL (0.35 mmol/L) during the first day of life.

The plasma urea nitrogen concentration decreases after birth as the infant synthesizes new protein, and the concentration does not begin to rise until tissue catabolism becomes prominent. The plasma amino acid concentration is low as a result of synthesis of tissue protein, although urinary excretion of amino acids may be quite high because of immaturity of the tubular reabsorptive mechanisms. The plasma urate concentration is high at birth, but the high clearance of urate soon reduces the plasma concentration below the adult value.

The serum thyroxine concentration of the healthy newborn, like that in the pregnant woman, is considerably higher than in the nonpregnant adult. After its birth, an infant secretes TSH, which causes a further increase in the

serum thyroxine concentration. The physiological hyperthyroidism gradually declines over the first year of life.

Childhood to Puberty. Many changes take place in the composition of body fluids between infancy and puberty. Most of the changes are gradual, and there are rarely abrupt changes to adult concentrations.

The plasma protein concentrations increase after infancy, and adult concentration values are attained by the age of 10. Serum IgG increases slightly out of proportion to the increase in concentration of α_2-globulin. The serum activity of most enzymes decreases during childhood to adult values by puberty or earlier, although the activity of ALT may continue to rise, at least in men, until middle age. Serum ALP activity is high in infancy but decreases during childhood and rises again with growth before puberty. The activity of the enzyme is better correlated with skeletal growth and sexual maturity than with chronological age; it is greatest at the time of maximum osteoblastic activity occurring with bone growth. The activity decreases rapidly after puberty, especially in girls. Total and LDL cholesterol concentrations increase during the rapid growth spurt also.

The serum creatinine concentration increases steadily from infancy to puberty parallel with development of skeletal muscle; until puberty, there is little difference in the concentration between sexes. The serum urate concentration decreases from its high at birth until age 7 to 10 years, at which time it begins to increase, especially in boys, until about age 16 years.

The Adult. Adult values are usually taken as the reference for comparisons with those of the young and elderly. The concentrations of most test constituents remain quite constant between puberty and menopause in women and between puberty and middle age in men.

During the midlife years, serum total protein and albumin concentrations decrease slightly. There may be a slight decrease in the serum calcium concentration in both sexes. In men, the serum phosphate decreases greatly after age 20 years; in women, the phosphate also decreases until menopause, when a sharp increase takes place. The serum ALP begins to rise in women at menopause, so that in elderly women activity of this enzyme may actually be higher than in men. The concentration of glucose in plasma 1 hour after a loading dose rises by 8 mg/dL (0.44 mmol/L) per decade.

Serum urate concentrations peak in men in their twenties and in women during middle age. Urea concentration increases in both sexes in middle age. Age does not affect the serum creatinine concentration in men but does increase the concentration in women. The serum total cholesterol and triglyceride concentrations increase in both men and women at a rate of 2 mg/dL (0.02 mmol/L) per year to a maximum between ages 50 and 60 years. The activity of most enzymes in serum is greater during adolescence than during adult life. This enhanced enzyme activity presumably reflects the greater physical activity of the adolescents.

Uric acid	10

From Wilding P, Rollason JG, Robinson D. Pattern of change for various biochemical constituents detected in well-population screening. Clin Chim Acta, 1972;41:375-87.

The Elderly Adult. The plasma concentrations of many constituents increase in women after menopause (Table 17-9).[54]

Renal concentrating ability is reduced in the elderly adult, so that creatinine clearance may decline by as much as 50% between the third and ninth decades. This decreased clearance is caused more by a decrease in urinary creatinine excretion as a result of decreased lean body mass than by altered renal function. The tubular maximum capacity for glucose is reduced. The plasma urea concentration rises with age, as does the urinary excretion of protein. The serum median IgG and IgM concentrations are reduced in the elderly although serum IgA concentrations in men increase slightly in the elderly.

Hormone concentrations are also affected by aging. However, changes in concentration are much less pronounced than an endocrine organ's response to stimuli. Triiodothyronine concentration decreases by up to 40% in persons older than 40 years of age. Although thyroxine secretion is reduced, the thyroxine concentration is not changed, because its degradation is also reduced. Yet the plasma parathyroid hormone concentration does decrease with age. Cortisol secretion is reduced, although the serum concentration may not be affected. The reduced secretion leads to a reduction in the urinary excretion of 17-hydroxycorticosteroids. 17-Ketosteroid excretion in the elderly adult is about half that of the younger adult. The secretion and metabolic clearance of aldosterone are decreased, with a reduction of 50% in the plasma concentration. The aldosterone response to sodium restriction is diminished. Basal insulin concentration is unaffected by aging but its response to glucose is reduced. In men, the secretion rate and concentration of testosterone are reduced after age 50 years. In women, the

concentration of pituitary gonadotropins, especially FSH, is increased in the blood and urine.

Estrogen secretion in women begins to decrease before menopause and continues at a greater rate after menopause, whereas gonadotropins show a feedback-mediated reciprocal rise. Serum concentrations of estrogens decrease by 70% or more, and urinary excretion of estrogens is decreased comparably. The decreased estrogen secretion may be responsible for the increase of serum cholesterol that occurs up to age 60 in women. Estrogen secretion in men, although always less than in women, declines with age.

Sex

Until puberty, there are few differences in laboratory data between boys and girls. After puberty the characteristic changes in the concentrations of the sex hormones, including prolactin, become apparent. After puberty, the serum activities of ALP, ALT, AST, CK, and aldolase are greater in men than in women. The higher activity of enzymes originating from skeletal muscle in men is related to their greater muscle mass. After menopause, the activity of ALP increases in women until it is higher than in men. Although total LD activity is similar in men and women, the activities of the LD-1 and LD-3 isoenzymes are higher, and LD-2 is less in young women than in men. These differences disappear after the menopause.

The concentrations of albumin, calcium, and magnesium are higher in men than women, but the concentration of γ-globulin is less. Blood hemoglobin concentrations are lower in women; thus, the serum bilirubin concentrations are also slightly lower. The increased turnover of erythrocytes in women leads to their having a higher reticulocyte count than in men. Serum iron is low during a woman's fertile years, and her plasma ferritin may be only one third the concentration in men. The reduced iron concentration in women is attributable to menstrual blood loss. In contrast, the serum copper concentration tends to be higher in women than men. Cholesterol and LDL cholesterol concentrations are typically higher in men than women, whereas the α-lipoprotein, apolipoprotein A-1, and HDL cholesterol concentrations are less. The plasma amino acid concentrations and the concentrations of creatinine, urea, and urate are higher in men than in women. The effect of age on the difference in concentrations of serum constituents between men and women is illustrated in Table 17-10.

Race

Differentiation of the effects of race from those of socioeconomic conditions is often difficult. Nevertheless, the total serum protein concentration is known to be higher in blacks than in whites. This is largely attributable to a much higher γ-globulin, although usually the concentrations of α_1- and β-globulins are also increased. The serum albumin is typically less in blacks than whites. In black men, serum IgG is often 40% higher and serum IgA may be as much as 20% higher than in white men.[7]

The activity of CK and LD is usually much higher in both black men and women than in whites. This effect presumably is related to the amount of skeletal muscle, which tends to be greater in blacks than whites. Because of their greater skeletal development, black children usually have a higher serum ALP at puberty than do white children. Amylase activity in West Indian immigrants to the United Kingdom is typically higher than in native Britons.

Carbohydrate and lipid metabolism differ in blacks and whites.[4] Glucose tolerance is less in blacks, Polynesians,

TABLE 17-10 Influence of Sex on Composition of Serum at Different Ages

From Leonard PJ. The effect of age and sex on biochemical parameters in blood of healthy human subjects. In: Siest G. Reference values in human chemistry. Basel: Karger, 1973:134-40.

Male values are higher than female except where indicated by a minus sign.

Native Americans, and Inuits than in comparable age- and sex-matched whites. This is substantiated by a plasma glucose 1 hour after glucose challenge that may be as much as 15 to 25 mg/dL (0.8 to 1.4 mmol/L) higher in blacks than whites. After age 40, the serum cholesterol and triglyceride concentrations are consistently higher in both white men and women than in blacks. The lipoprotein (Lp) (a) concentration in blacks may be twice as high as in whites. These may be dietary rather than racial factors, because the concentration of plasma lipids has been shown to be different for the same racial group in different parts of the world. The blood hemoglobin concentration is as much as 10 g/L higher in whites than blacks. Black Americans of both sexes have lower leukocyte counts than white Americans, largely caused by a lower number of granulocytes, but their monocyte count is also less. Some of the indigenous groups of the Pacific (e.g., Maoris of New Zealand) have notably higher mean serum urate concentrations than white populations.

Environmental Factors

Environmental factors that affect laboratory results include altitude, ambient temperature, and place of residence.

Altitude

In individuals living at a high *altitude,* the blood hemoglobin and hematocrit are greatly increased because of reduced atmospheric PO_2.[14] Erythrocyte 2,3-diphosphoglycerate is also increased, and the oxygen dissociation curve is shifted to the right. The increased erythrocyte concentration leads to an increased turnover of nucleoproteins and excretion of urate. The fasting, basal concentration of growth hormone concentration is high in individuals living at a high altitude, but the concentrations of renin and aldosterone are decreased in healthy individuals. Plasma sodium and potassium concentrations are typically unaffected by high altitude although the osmolality is reduced. The serum concentrations of C-reactive protein, transferrin, and β_2-globulin are notably increased with transition to a high altitude. The urinary concentration and clearance are decreased at high altitudes. Complete adaptation to a high altitude takes many weeks whereas adjustment to lower altitudes takes less time.

Ambient Temperature

Ambient temperature affects the composition of body fluids. Acute exposure to heat causes the plasma volume to expand by an influx of interstitial fluid into the intravascular space, and by reduction of glomerular filtration. The plasma protein concentration may decrease by up to 10%. Sweating may cause salt and water loss, but usually there are no changes in the plasma sodium and chloride concentrations. Plasma potassium concentration may decrease by as much as 10% as potassium is taken up by the cells. If sweating is extensive, hemoconcentration rather than hemodilution may occur.

Place of Residence

The geographical location where individuals live may affect the composition of their body fluids. Thus a statistically significant increase in the serum concentrations of cholesterol, triglycerides, and magnesium has been observed in people living in areas with hard water. Trace element concentrations are also affected by locale, for example, in areas where there is much ore smelting, serum concentrations of the trace elements involved may be increased. Carboxyhemoglobin concentrations are higher in areas where there is much heavier automobile traffic than in rural areas (as was true for blood lead in the 1970s in the United States). Individuals who primarily work indoors typically have lower concentrations of 25-hydroxy vitamin D than those who work outdoors, leading to higher serum calcium concentrations and greater urinary excretion of calcium.

Long-Term Cyclical Changes

Long-term cyclical changes also affect laboratory results. Seasonal influences and the menstrual cycle are examples of such changes.

Seasonal Influences

Seasonal influences on the composition of body fluids are small compared with those related to changes in posture or misuse of a tourniquet.[35] Probable factors are dietary changes as different foods come into season and altered physical activity as more or different forms of exercise become feasible. Evaluations of seasonal variation are difficult because they depend on the definition of a season and on the magnitude of temperature change from one season to another. Day-to-day variability in the composition of body fluids is greater in summer than winter. Nevertheless, biological variability is in general only a little greater than analytical variability.

In summer in the northern hemisphere, the blood volume increases in association with the higher temperature. In winter the plasma protein increases by as much as 10%. In contrast, the γ-globulin may increase by as much as 50% in summer. Serum urate concentrations appear to be 5% to 7% higher in summer than in winter. Urea concentrations are also higher in winter than in summer. Serum triglyceride concentrations are up to 10% higher in summer, whereas the serum cholesterol has been reported to be up to 50 mg/dL (1.3 mmol/L) higher in men and 30 mg/dL (0.7 mmol/L) higher in women in winter than in summer. The increased winter cholesterol concentration has been attributed to less physical exercise, greater food intake, and lower amounts of sunshine. However, similar changes in animals suggest that humoral factors may also be involved. Activities of serum enzymes arising from skeletal muscle are higher in summer than in winter, presumably as a result of increased physical activity. The increase of serum lactate dehydrogenase may be as much as 20%.

Calcium metabolism is affected by an individual's exposure to sunlight. Dehydrocholecalciferol in the skin is

TABLE 17-11 Seasonal Effects on Composition of Serum

Constituent	Concentration		
	Highest	Lowest	% Difference Between High and Low

converted by ultraviolet irradiation to cholecalciferol, which is further metabolized in the liver and kidney to 1,25-dihydroxycholecalciferol. The calcium concentration in serum is increased along with its elimination in urine.[22] Seasonal changes appear to affect other endocrine systems as well. A lower plasma glucose concentration may be observed and glucose tolerance is improved during summer. Serum concentrations of thyroid hormones are generally unaffected but the serum concentration of triiodothyronine is decreased by 20% in summer and its urinary excretion is increased. The excretion of metabolites of adrenal hormones usually is greater in summer than in winter. This could be attributable to greater physical activity.

Exposure to sunshine for a weekend during summer may cause enough photodegradation of bilirubin to reduce the serum concentration by 20%. Protracted exposure to sun during the summer leads to a consistently lower bilirubin concentration than during winter. Some seasonal effects on the composition of body fluids are listed in Table 17-11.

Influence of Menstrual Cycle

The plasma concentrations of many female sex hormones and other hormones are affected by the menstrual cycle (see also Chapters 50 to 53).[58] Thus the plasma corticosterone concentration is as much as 50% higher in the luteal phase than in the follicular phase. The urinary excretion of 17-hydroxycorticosteroids reaches a peak at midcycle. Plasma androstenedione concentration and plasma aldosterone concentration increase from the follicular phase to the luteal phase of the menstrual cycle. On the preovulatory day, the aldosterone concentration may actually be twice that of the early part of the follicular phase. The change in renin activity is almost as great. These changes are usually more pronounced in women who retain fluid before menstruation. Urinary catecholamine excretion increases at midcycle and remains high throughout the luteal phase. These changes within the menstrual cycle make it essential to do repetitive measurements on women at the same time during the cycle.

The plasma cholesterol and triglyceride concentrations tend to be highest at midcycle, corresponding to the time of maximum estrogen secretion. The cyclical variation in cholesterol is not observed with anovulatory cycles. The total protein and albumin concentrations decrease at the time of ovulation but then increase again. The plasma fibrinogen concentration decreases greatly at menstruation. The serum calcium correlates with changes in albumin. Serum phosphate is reduced at the time of menstruation, although the creatinine and urate concentrations are highest at this time and are lowest toward the end of the intermenstrual period.

The plasma iron concentration may be very low with the onset of menstruation; the magnesium concentration is least at this point of the cycle. Plasma sodium and chloride concentrations increase up to the onset of menstruation but may fall by 2 mmol/L with the postmenstrual diuresis.

The plasma ascorbic acid concentration is low at the time of ovulation, whereas that of folate is unaffected by the menstrual cycle. Serum CK activity may be slightly reduced at the time of ovulation, but the activities of other enzymes appear to be unaffected by the menstrual cycle.

Underlying Medical Conditions

Some general clinical conditions have an effect per se on the composition of body fluids. These conditions may exist in addition to the primary complaint that prompted a patient's admission to the hospital. For example, obesity, blindness, fever, shock and trauma, and transfusions and infusions all affect laboratory results.

Obesity

The serum concentrations of cholesterol, triglycerides, and β-lipoproteins are positively correlated with obesity.[47] One

study in twins has shown that for an average increase of 7.3% in body mass index there were increases of 2.5% in total cholesterol concentration, 3% in LDL cholesterol concentration, and 18.2% in triglyceride concentration.[9] The increase in the concentration of cholesterol is attributable to LDL cholesterol because the HDL cholesterol is typically reduced. The serum urate concentration is also correlated with body weight, especially in individuals weighing more than 80 kg.[39] Serum LD activity and glucose concentration increase in both sexes with increasing body weight.[47] In men, serum AST, creatinine, total protein, and blood hemoglobin concentration increase with increasing body weight. In women, serum calcium increases with increasing body weight. In both sexes, serum phosphate decreases with increased body mass.

Cortisol production is increased in obese individuals. However, increased metabolism maintains the serum concentration unchanged so that urinary excretion of 17-hydroxycorticosteroids and 17-ketosteroids is increased. Because the growth hormone concentration is reduced in obese individuals, it responds poorly to the normal challenges. Plasma insulin concentration is increased, but glucose tolerance is impaired in the obese (see Chapter 25). Although the serum thyroxine concentration is unaffected by obesity, the serum triiodothyronine correlates significantly with body weight and increases further with overeating. In obese men, the serum testosterone concentration is reduced.

The fasting concentrations of pyruvate, lactate, citrate, and unesterified fatty acids are higher in obese individuals than in those of normal body weight. Serum iron and transferrin concentrations are low.

Gastric juice volume and acid output are increased in obese individuals.

Blindness

With blindness, the normal stimulation of the hypothalamic-pituitary axis is reduced. Consequently, certain features of hypopituitarism and hypoadrenalism may be observed.[5] In some blind individuals, the normal diurnal variation of cortisol may persist; in others it does not. Urinary excretion of 17-ketosteroids and 17-hydroxycorticosteroids is reduced. Plasma sodium and chloride are often low in blind individuals, probably as a result of reduced aldosterone secretion. Plasma glucose may be reduced in blind people, and insulin tolerance is often less. The excretion of urate is reduced. Renal function may be slightly impaired, as evidenced by slight increases in serum creatinine and urea nitrogen.

Negative nitrogen balance may occur in blind people, and the serum protein concentration may be reduced. The serum cholesterol is frequently increased, and bilirubin concentration may also exceed the upper limit of normal. The diurnal variation of serum iron is often lost.

Pregnancy

Many changes in the concentrations of analytes occur during pregnancy and proper interpretation of test results is dependent on knowledge of the duration of pregnancy (see Chapter 54).

Substantial hormonal changes occur during pregnancy including several not normally associated with reproduction. Many of the changes are related to the great increase in blood volume that occurs during pregnancy from about 2600 mL early in pregnancy to 3500 mL at about 35 weeks. This hemodilution reduces the concentration of the plasma proteins. However, the concentration of some transport proteins including ceruloplasmin and thyroxine-binding globulin is increased, resulting in increased concentrations of copper and thyroxine. The concentrations of cholesterol and triglycerides are notably increased. In contrast, pregnancy creates a relative deficiency of iron and ferritin.

Urine volume increases during pregnancy so that it is typically 25% greater in the third trimester than in the nonpregnant woman. The glomerular filtration rate increases by 50% during the third trimester. This results in increased urinary excretion of hydroxyproline and increased creatinine clearance.

Pregnancy triggers many physiological stress reactions and is associated with increased concentrations of acute-phase reactant proteins. The erythrocyte sedimentation rate increases fivefold during pregnancy.

Stress

Physical and mental stress influence the concentrations of many plasma constituents. Anxiety stimulates increased secretion of aldosterone, angiotensin, catecholamines, cortisol, prolactin, renin, somatotropin, TSH, and vasopressin. Plasma concentrations of albumin, cholesterol, fibrinogen, glucose, insulin, and lactate also increase.

Fever

Fever provokes many hormonal responses.[44] Hyperglycemia occurs early and stimulates the secretion of insulin, which improves glucose tolerance; but insulin secretion does not necessarily reduce the blood glucose concentration because increased secretion of growth hormone and glucagon also occurs. Fever appears to reduce the secretion of thyroxine, as do acute illnesses even without fever. In response to increased corticotropin secretion, the plasma cortisol concentration is increased and its normal diurnal variation may be abolished. The urinary excretion of free cortisol, 17-hydroxycorticosteroids, and 17-ketosteroids is increased. As acute fever subsides, or if it lessens but still persists for a prolonged period, the hormone responses diminish.

Glycogenolysis and a negative nitrogen balance occur with the onset of fever. These are prompted by the typically decreased food intake and wasting of skeletal muscle that accompany fever. Although there is usually an increase in the blood volume with fever, the serum concentrations of creatinine and urate are usually increased. Aldosterone secretion is increased with retention of sodium and chloride. Secretion of antidiuretic hormone also contributes to the retention of water by the kidneys. Increased synthesis of protein

occurs in the liver, and the plasma concentrations of acute-phase reactants and glycoproteins are increased.

Fever accelerates lipid metabolism. The serum concentrations of cholesterol, nonesterified fatty acids, and the other lipids may decrease initially, but within a few days the free fatty acid concentration may increase. Fever is often associated with a respiratory alkalosis caused by hyperventilation. This pH increase causes a reduction of the plasma phosphate concentration, with an increased excretion of phosphate and other electrolytes.[2] Serum iron and zinc concentrations decline with accumulation of both elements in the liver. The copper concentration increases because of increased production of ceruloplasmin by the liver. Some representative changes in serum composition induced by fever are listed in Table 17-12.

Shock and Trauma

Regardless of the cause of shock or trauma, certain characteristic biochemical changes result.[11] For example, corticotropin secretion is stimulated to produce a threefold to fivefold increase in the serum cortisol concentration. The 17-hydroxycorticosteroid excretion is greatly increased, although the excretion of 17-ketosteroids and metabolites of adrenal androgens may be unaffected. Aldosterone secretion is stimulated. Plasma renin activity is increased, as are the secretions of growth hormone, glucagon, and insulin. Anxiety and stress increase the excretion of catecholamines. The stress of surgery has been shown to reduce the serum triiodothyronine by 50% in patients without thyroid disease.

The general metabolic response to shock includes the normal response to stress with mobilization of lipids, although the serum triglyceride concentration is not usually affected. Following acute myocardial infarction and other cardiac events there tend to be notable decreases in LDL and HDL cholesterols, and apolipoprotein B and A-I concentrations with an increase in the triglyceride concentration. Surgical procedures and intercurrent illnesses produce similar effects. Even minor illnesses, such as colds, can affect lipid concentrations. The concentrations of lipids revert to normal within 1 month of the event. Plasma glucose concentration is increased in response to stress, and glucose tolerance is reduced.

Immediately after an injury, there is loss of fluid to extravascular tissue with a resulting decrease in plasma volume. If the decrease is enough to impair circulation, glomerular filtration is diminished. Diminished renal function leads to the accumulation of urea and other end products of protein metabolism in the circulation. In burned patients, serum total protein concentration falls by as much as 0.8 g/dL because of both loss to extravascular spaces and catabolism of protein. Serum α_1-, α_2-, and γ-globulin concentrations increase, but not enough to compensate for the reduced albumin concentration. The plasma fibrinogen concentration responds dramatically to trauma and may double in 2 to 8 days after surgery. The concentration of C-reactive protein rises at the same time.

The muscle damage associated with the trauma of surgery will increase the serum activity of enzymes originating in skeletal muscle, and this increased activity may persist for several days. Typical alterations in activity of serum enzymes following surgery are illustrated in Table 17-13. Increased tissue catabolism requires increased oxygen consumption and also leads to the production of acid metabolites. Thus blood lactate may increase twofold to threefold. With tissue anoxia and impairment of renal and respiratory function, a metabolic acidosis develops. With tissue destruction, there is increased urinary excretion of the major biochemical components of skeletal muscle.

Transfusion and Infusions

The protein-rich fluid lost from the intravascular space after trauma is replaced with protein-poor fluid from the interstitial spaces. Subsequently, this is replaced by a fluid similar in composition to plasma. Transfusion of whole blood or plasma raises the plasma protein concentration; the amount

TABLE 17-12 Effect of Fever on Composition of Serum

		Concentration After Induction of Fever

From Beisel WR, Goldman RF, Joy RJT. Metabolic balance studies during induced hyperthermia in man. J Appl Physiol 1968;24:1-10.

of increase depends on the amount of blood administered. Serum LD activity, primarily LD-1 and LD-2 isoenzymes, is increased by the breakdown of transfused erythrocytes. Transfusions to replace blood lost because of injury reduce sodium, chloride, and water retention precipitated by the injury. Serum iron and transferrin concentrations are reduced immediately after an injury, but extensive blood transfusions can lead to siderosis and an increased serum iron concentration. Serum potassium may increase with transfusion of stored blood.

Infusions of glucose solutions usually result in a reduction of both the plasma phosphate and potassium concentrations because these compounds are taken up by the erythrocytes. Infusions of solutions of albumin may increase plasma ALP activity if the albumin has been prepared from placentas. Because of the possible influence of infused components on the concentration of circulating constituents, it is inadvisable to collect blood for analysis less than 8 hours after infusion of a fat emulsion or 1 hour after infusion of carbohydrates, amino acids, and protein hydrolysates or electrolytes.

BIOLOGICAL VARIABILITY*

Data from studies of biological variation may be used to assess the importance of changes in test values within an individual from one occasion to another, determining the appropriateness of reference intervals and, in conjunction with data from analytical variation, establish laboratory analytical goals.[15-17] Application by clinicians of information on biological variability could enhance their ability to precisely identify important changes in test results in their patients.

OVERVIEW

Categories of biological variation include (1) within an individual and (2) between individuals. The change of laboratory data around a hemostatic set point from one occasion to another within one person is called within-subject or intraindividual variation (Table 17-14). The difference

*Note: The authors have based much of their discussion of biological variability on CG Fraser's book: Biological variation; From principles to practice. Washington DC: AACC Press, 2–1:1-151. It should be consulted for further details.

TABLE 17-14 Comparison of Intraindividual and Interindividual Variations and Indices of Individuality

Analyte	Intraindividual Variation (%)	Interindividual Variation (%)	Index of Individuality
Alanine aminotransferase	24.3	41.6	0.58
Albumin	3.1	4.2	0.74
Alkaline phosphatase	32.6	39.0	0.84
Bilirubin	25.6	30.5	0.85
Calcium	1.9	2.8	0.68
Chloride	1.2	1.5	0.80

Reprinted with permission of AACC Press, from Fraser CG, Biological variation: From principles to practice. Washington DC: AACC Press, 2001.

between the set points of different individuals is called interindividual variation. The average intraindividual variability varies greatly for different analytes, even within the same biochemical class of compounds (e.g., 6.1% for total cholesterol, 7.4% for HDL cholesterol, 9.5% for LDL cholesterol, and 22.6% for triglycerides). The major factors influencing the reported intraindividual and interindividual variability are primarily the number of individuals in a study, the standardization (or lack thereof) of patient preparation and specimen collection conditions, the number of measurements per individual, and the homogeneity of the studied population.

Often, biological variability influences clinical decisions. For example, Mogadam et al have shown that intraindividual variability in LDL concentrations led to 10% of subjects moving from high risk for cardiovascular events status to normal or vice versa.[38] Where clinicians rely inappropriately on the upper and lower limits of the reference interval as finite decision points for treatment, this will result in some patients receiving unnecessary treatment and others, who should be candidates for treatment, going untreated and potentially lost to follow-up because their test values suggested that the individuals were healthy.

The test values in a healthy population used to derive a conventional reference interval are subject to the variety of influences including endogenous, exogenous, genetic or ethnic, and laboratory factors discussed above. The statistical approach used to calculate the interval also has considerable influence on the derived reference interval (see Chapter 16). No individual has test results that would span the entire reference interval. Indeed all the results within a healthy individual typically encompass only a small part of most reference intervals. Stratification into more appropriate intervals for subpopulations is sometimes required. The most typical stratifications are based on sex and age. Sinton et al[48] have advocated that separate reference intervals are justified when the difference between the means of the potentially different populations (e.g., men and women or blacks and whites) is greater than 25% of the 95% reference interval of the entire population. An alternative approach to define whether stratification is appropriate is that of Harris and Boyd, which involves calculation of the standard deviations of all of the results from each of the potentially different populations and if the standard deviation of one is more than 1.5 times another stratification is justified.[25]

Inherent in any reported laboratory test results on patients are influences of (1) biological variation, (2) inherent analytical error, (3) preanalytical and postanalytical sources of variation, and (4) possible pathophysiological alterations. When repeated measurements are made over time in one individual, even under standardized conditions, there is a considerable variability in the test results. The variability within the individual is attributable to both analytical and intraindividual factors but the intraindividual (within-subject) variability is typically less than the variability among a group of individuals. This means that when analytical variability is constant, a statistically significant change in the test results in one individual might occur yet all the results could still lie within the reference interval established from the results obtained from many individuals. Many studies have demonstrated remarkable constancy over the years in intraindividual variability. For those analytes that are influenced by the endocrine system, the variation tends to be even less than for those that have no hormonal regulation, especially those that are affected by dietary factors. In general, biological variability is only slightly affected by age[18] or by diseases that do not directly cause abnormal concentrations of a specific analyte.[27,28]

Delta Check

When a patient's clinical condition is generally stable and differences between repeated test results are small, the difference between successive results may be used as a form of quality assurance (see Chapter 19). Most physicians arbitrarily decide when there is a clinically significant difference between repeated measurements of the same analyte. However, it is possible to address the issue more systematically and logically. The *delta check* concept is applied to two successive values regardless of the time interval between them. Delta check values are typically generated in one of two ways: the first is derived from the differences between the collected consecutive values for an analyte in many individuals, which are then plotted in a histogram with the central 95% or 99% of all values used to identify a clinically significant change in values. Delta checks may involve the absolute difference or the percent change between the consecutive numbers. The second approach to establishing the delta relies on a laboratorian's or clinician's best estimate of an appropriate delta to yield a manageable number of flagged results for follow-up. A more refined means of using patient data for assessing statistically significant changes is through rate checks that involve dividing a delta check value by the time interval between successive measurements. Several different delta check methods have been proposed.[34] Delta checks have been based on (1) delta difference: current result – previous result; (2) delta percent change: (current – previous result) × 100%/previous result; (3) rate difference: delta difference/delta time; and (4) rate percent change: delta percent change/delta time (where delta time is the interval between the current and previous specimen collection times). Some laboratory information systems embody delta checks in the reporting of test results but usually in the simplest way, as in delta difference or delta percent change.

In healthy individuals and in stable patients, the delta value between any two results should be small. Acceptable delta values may be calculated within a population of healthy individuals and then averaged, with the average used as a guide to determine whether a difference of possible clinical significance had occurred between serial measurements in patients. An alternative approach is to use the more refined reference change value (RCV), or critical difference, concept.

Calculating Total Variation

To determine what confidence should be placed in a test result it is useful to evaluate the variability of test values. The factors influencing a test value are preanalytical, analytical, and within an individual. As the sources of variation (squares of the standard deviations) are additive, the total variation (SD_T^2) for any one laboratory result is

$$SD_T^2 = SD_P^2 + SD_A^2 + SD_I^2$$

where

SD_P = Standard deviation of preanalytical variation
SD_A = Standard deviation of analytical variation
SD_I = Standard deviation of within individual biological variation

It is possible to substitute the coefficient of variation for the standard deviation in the above equation. If the conditions of patient preparation, sample collection, and sample handling are standardized, preanalytical variation is minimized and the total variation is then determined by the combined influence of the analytical and intraindividual variations, thus:

$$CV_T = \left(CV_A^2 + CV_I^2\right)^{1/2}$$

Reference Change Values

To determine whether the difference between consecutive results for a single analyte in a patient might have clinical significance, Harris and Yasaka developed the concept of *reference change values.*[26] *An RCV,* also known as *critical difference,* is the value that must be exceeded before a change in consecutive test results is statistically significant at a predetermined probability. The concept introduces a scientific approach to an area where clinicians have largely relied on their intuition and experience. Historically, clinicians' impressions of clinically significant differences been results have varied quite markedly. Fraser et al[18] have shown that systematically calculated critical differences for many analytes tend to be less than physicians' assumptions of clinically significant differences.

An RCV takes into account both analytical and within-individual variations that were discussed above. It is calculated using the following equation

$$RVC = 2^{1/2} \times Z \times \left(CV_A^2 + CV_I^2\right)^{1/2}$$

where Z = Z-score (also called standard normal deviate). Z-scores vary with the desired probability for the change. The Z-scores for different probabilities may be derived from statistical tables. For the widely used probability of 95% for clinical laboratory decisions, the Z-score is 1.96. When inserted in the formula above the formula becomes

$$RVC = 2.77 \times \left(CV_A^2 + CV_I^2\right)^{1/2}$$

In practice, a Z-score of 1.96 for a 95% probability is used to identify a significant RCV. A Z-score of 2.58 is used for a 99% probability to ensure an even more significant RCV. The higher the probability used in the calculation the greater the likelihood that all identified changes will be true changes. Yet the greater certainty with the higher probability may make some physicians believe that the change is obvious and that such large RCVs may mask trends in test values. The CV_A used for the calculation should be appropriate for the range of test values, as low analytical variability enhances the likelihood of calculated changes being statistically significant. The probability of change is then largely influenced by intraindividual variation, CV_I. To enhance the utility of the RCV intraindividual, variability should also be minimized with standardization of patient preparation and specimen collection and processing practices. Standardization is more readily achieved in hospital practice, where uniform timing of collections by trained phlebotomists is often possible, than in outpatient practices.

The change in values between successive measurements in a hospitalized patient is generally higher than in the values reported in the literature derived from studies of healthy individuals because of the change in the patient's medical condition and its response to treatment. RCVs are not constant and a significant change is likely to be smaller over the short term than over a longer time span. Thus application of RCVs from healthy individuals derived over a short time will identify an inappropriately large number of apparently significant changes in hospitalized patients. CV_I varies between individuals so that calculations using the mean CV_I also flag a disproportionately large number of significant changes. Table 17-15 shows the effect of using different probabilities of significant changes.

Index of Individuality

Although it would be preferable if the range of values in an individual when healthy could be used as the reference for the same individual when he or she is ill, this is largely impractical. The less specific reference interval derived from many individuals must be used as a guide to determine whether a specific result is abnormal. The *index of individuality* (II) allows a comparison of total within-subject (intraindividual) variation to between-subject (interindividual) variation. It is calculated as the ratio of the total intraindividual variation to interindividual biological variation as

$$II = \frac{\left[CV_A^2 + CV_I^2\right]^{1/2}}{CV_G}$$

where CV_A is the analytical variability, CV_I the intraindividual variability, and CV_G the interindividual variability. In clinical practice for most analytes, CV_A is small in comparison with CV_I or CV_G and can be ignored and the formula for II is thus simplified to

$$II = \frac{CV_I}{CV_G}$$

A low index of individuality indicates that an analyte has marked individuality and a high index indicates that

TABLE 17-15 Significance of Changes in Serial Results: Probability That Changes Between Successive Values Are Significant (%)

		PROBABILITY					
Analyte	**Units**	**60**	**70**	**80**	**90**	**95**	**99**
Alanine aminotransferase	U/L	3	5	8	13	16	23
Albumin	g/L	<1	1	2	3	4	5
Alkaline phosphatase	U/L	4	9	13	20	26	36
Amylase	U/L	2	5	8	13	16	23
Bilirubin	mmol/L	<1	1	2	3	4	6
Calcium	mmol/L	0.02	0.04	0.06	0.09	0.12	0.17
Chloride	mmol/L	1	2	3	4	5	7
Cholesterol	mmol/L	0.2	0.3	0.5	0.8	1.1	1.5

an analyte has little individuality. Examples of indices of individuality for several analytes are listed in Table 17-14. Harris[24] has demonstrated that it is only appropriate to use the reference interval for an analyte to make clinical decisions when CV_I/CV_G is greater than 1.4. When II is less than 0.6, conventional population reference values are of little value and may be misleading. Little variation in test values for an analyte within one person (i.e., a high index of individuality) means that an individual could have considerable changes in laboratory data that might have clinical significance for him or her, yet all these values could fall within the population reference interval. In theory, such analytes are of little use for the diagnosis of disease unless the changes are markedly abnormal but would be better suited for monitoring the progress of a disease or its response to treatment where the differences between consecutive measurements are used to identify a change in a patient's status.

Index of Heterogeneity

The *index of heterogeneity* (IH) provides a means of determining whether the individuals within a population have similar within-individual variation for a given analyte. It is is defined as the ratio of CV of $(SD_A^2 + SD_I^2)^{1/2}$ to $[2/(n-1)]^{1/2}$ where A and I are the analytical and within-subject variations and n is the number of specimens per subject. The higher the index of heterogeneity the greater the intraindividual variation.

Reliability Coefficient

The *reliability coefficient* (R) is the ratio of between-subject variation to total variation. This is another measure of individuality. It is calculated as the between-individual variance divided by the total variation.

$$R = \frac{CV_G^2}{CV_A^2 + CV_I^2 + CV_G^2}$$

The reliability coefficient will always be between 0 and 1. If it approaches 1, this means that there is very little variation of results over time within one individual, indicating that great confidence can be placed in a single result and that repeated measurements are unnecessary.

Quality Specifications for Total Error Allowable

Analytical variations may increase the number of results in a healthy population outside a previously established reference interval. A positive analytical bias increases the number of high values and a negative bias decreases the number below the lower reference limit. It is possible to link the maximum tolerable analytical bias to biological variability.[17] The relationship below is derived on the assumption that the maximum acceptable bias is less than one quarter of the sum of the intraindividual and interindividual variations within a population.

$$\text{Analytical bias} < 0.25 \times \left(CV_I^2 + CV_G^2\right)^{1/2}$$

By substituting different factors in the above formula different targeted analytical biases can be identified. If less analytical bias is deemed to be appropriate (e.g., one fifth of the total biological variation instead of one quarter), 0.20 would be substituted for 0.25. It has been suggested that analytical precision should be less than one half of the mean intraindividual variation ($CV_A = <0.50\ CV_I$). Total error is derived from the sum of imprecision and bias. From the formula above

$$\text{Total allowable analytical error} < 1.65 \times 0.50 \times CV_I + 0.25 \times \left(CV_I^2 + CV_G^2\right)^{1/2}$$

The factor 1.65 is derived from 90% of the distribution of results excluding the highest and lowest 5% of values. Again, substituting different values for 0.50 and 0.25 above allows different goals to be established.

Other formulas have been used to determine quality specifications for bias. Generally, analytical bias should be less than one quarter of interindividual biological variation.

$$B_A < 0.250 \times \left(CV_I^2 + CV_G^2\right)^{1/2}$$

But optimum performance is also defined by substituting 0.125 for 0.250 in the above formula and minimum performance defined by substituting 0.375 for 0.250. When the factor 0.125 is used, 1.8% of values are outside one reference limit and 3.3% outside the other. When 0.375 is used 1.0% values are outside one reference limit and 5.7% outside the other.[17] Fraser has stated that the lower number should be used when desirable performance standards are easily attained and 0.375 should be used when performance goals are not readily attainable with current procedures.[17] Most of the literature has reported total error in terms of the sum of bias plus 1.65 times the precision (TE_A = Bias + 1.65 SD or CV of interindividual variation).

Biological variation has been included in a goal to determine analytical interference.[20] The goal specifies that

$$\text{Interference (\%)} < CV_I - (1.96\, CV_A + SE)$$

where *SE* represents the percentage systematic error (inaccuracy).

Assessment of Mode of Reporting Test Results

The RCV concept is used to determine the most appropriate mode to report several analytes where several possibilities exist. For example, the amount of an analyte in urine could be reported in terms of concentration, absolute amount per unit of time, or the amount relative to that of creatinine. The mode with the smallest relative change value is the most informative. Data on analytical and intraindividual variation together with RCV can pinpoint the most appropriate type of specimen for certain analyses. Howey et al[29] studied random, early morning, and 24-hour urine specimens to determine the most appropriate means to monitor microalbuminuria. The first morning specimen became the preferred specimen because of its smallest within-individual variation, smallest heterogeneity in intraindividual variances, and smallest RCV between consecutive measurements.

Data on biological variability are used to assist in the selection of the most appropriate test in a given situation. For example, creatinine clearance and urine creatinine have less intraindividual variation than serum creatinine so that creatinine clearance is a better choice than serum creatinine for initial assessment of renal function in an individual but the lower RCV for serum creatinine make this test better for monitoring individuals. However, the need for a urine collection reduces the practicality of using clearance in the initial assessment of renal function. Studies to determine whether the GFR calculated from the serum creatinine concentration might enhance the utility of the serum measurement still have to be performed.

CHAPTER 18

Clinical Laboratory Informatics*

Kent A. Spackman, M.D., Ph.D.

Many authors have observed that a clinical laboratory produces information as its main product. Information technology plays a key role in the effective management of information, and therefore a certain level of knowledge and skill in information technology and informatics has become essential to clinical laboratory professionals.[2,3,5] *Health informatics* may be defined as the principles and practice of effective information management for health, including the collection, processing, and distribution of health information about individuals and populations. *Clinical laboratory informatics* deals with the total testing process, from the time a clinician perceives a requirement for a test until the time he or she receives and interprets the result of that test. The computer is an important tool for managing this flow of information, but informatics addresses more than just computing; indeed, the most important aspects of informatics often depend on workflow and human factors, rather than on computer hardware or software. Still, a basic understanding of general computing concepts is fundamental to an ability to recognize and solve problems in the effective use of information.

COMPUTING FUNDAMENTALS

This section provides an introduction to informatics concepts, starting with definitions, progressing to hardware descriptions, and finishing with observations regarding the rate of developmental change in computing.

COMPUTER BASICS

Any computer system consists of *hardware,* the physical devices connected together forming the computer, and *software,* the set of programs and instructions that tell the hardware what to do. A *program* consists of a set of ordered commands, which the computer hardware can execute in sequence to accomplish a task. *System programs* are designed to support general tasks, such as reading from an input device, displaying on a screen, printing, or allowing a user to log in, and basically making the computer "run." A collection of essential system programs is called the *operating system.* Microsoft Windows and Linux are examples of operating systems. Programs that are designed to do special purpose tasks, such as running a laboratory information system, are called *application programs.* When the program supports interaction with a person (the *user*), it is called a *user application.* Application programs must be compatible with the operating system on which they run. We say the application runs *on top of* the operating system. Upgrades to either the operating system or the application program may introduce incompatibilities, which may or may not be known to the software suppliers, so a new version of either application software or operating system requires testing before the system can be used with confidence. The combination of hardware, operating system, and applications, together with the persons who use them and the processes that they follow, is often called an *information system.* It cannot be overemphasized that the most important determinants of success of an information system are the people and processes, not the hardware and software.

Selecting the hardware correctly is generally a matter of determining or specifying capacity and compatibility with standards. Hardware capacity can usually be simplified to two aspects: size and speed.

*The author gratefully acknowledges the original contribution by Dr. Franklin R. Elevitch, on which portions of this chapter are based.

Size

The smallest quantity of computer information is the *bit*, or binary digit, meaning either a 0 or a 1. Because information represented and stored this way uses such discrete digits, it is called *digital*, in contrast to information represented using essentially unlimited levels of gradation, a representation called *analog*. Putting several bits together in a string results in a series of zeroes and ones; each such combination can be used to represent a different numeral or alphabetic character. By convention, a *byte* consists of eight bits. There are 2^8 or 256 different combinations of bits that can be represented by one byte. Computers can interpret these 256 combinations according to standards such as the American Standard Code for Information Interchange (ASCII). Because ASCII assigns one byte to each typewritten character, a useful rough estimate of the size of a document equates the number of typewritten characters with the number of bytes required to store it. Documents containing special characters or symbols (accents, umlauts, etc.) may be stored using the Unicode standards, which often use more than one byte per character.

Size, in computer terms, uses idiosyncratic units in addition to the bit and byte. Outside the world of computing, the prefixes kilo, mega, giga, and tera ordinarily refer to 10^3, 10^6, 10^9, and 10^{12}, respectively. However, when used with *byte*, they refer instead to 2^{10}, 2^{20}, 2^{30}, and 2^{40}. That is, a kilobyte is not 1000 bytes but 1024 bytes. The reason is that *addresses*, the numbers that refer to the location of digital data, are binary numbers, so a kilobyte is the total number of bytes that can be addressed by a ten bit address, and it carries the kilo prefix because it is the power of 2 closest to 1000. Likewise a megabyte is 1,048,576 bytes because it is the power of 2 closest to 1,000,000, and represents the number of locations addressable by 20 bits.

Prefix	Computer Storage Meaning	Usual Meaning
kilo	$2^{10} = 1024$	10^3
mega	$2^{20} = 1{,}048{,}576$	10^6
giga	$2^{30} = 1{,}073{,}741{,}824$	10^9
tera	$2^{40} = 1{,}099{,}511{,}627{,}776$	10^{12}

Speed

In computer terminology, *speed* has two chief varieties: *clock speed* and *bandwidth*. Clock speeds, which give an indication of how fast a processor runs, have units of Hertz (Hz), or cycles per second. In this case, standard prefix meanings are used, so one megaHertz is 10^6 cycles per second. The simplest computer instructions require one clock cycle to be executed, so a processor with a clock speed of one megaHertz would be able to execute one instruction in one microsecond, and a gigaHertz processor could execute one instruction in a nanosecond. *Bandwidth* refers to the amount of data that can be transmitted per unit time. We might expect it to be measured in bytes per second (or kilobytes, megabytes, gigabytes, and terabytes per second), but curiously it has instead been traditionally measured in mega*bits* per second, with mega meaning 10^6, not 2^{20}.

Hardware

As computers have become more integrated, miniaturized, and streamlined, more and more of the internal hardware has become integrated onto a single silicon chip. As a result, it is useful to separately consider the parts of the system that are relatively modular and can be selected by the user, and the parts that are integrated into the "box," which is mainly hidden from the user.

Inside the box, there is a *central processing unit* (CPU), which is where the clock is located that determines processor speed and where the software instructions are executed. The CPU must fetch the instructions from memory. A type of memory that is very fast and located close to the CPU, usually on the same chip, it is called *cache* memory; the ordinary type of memory is called *random access memory* (RAM). Memory should be distinguished from *storage*. Generally speaking, memory can be quickly accessed, for both reading and writing, but its contents disappear when the power is turned off. By contrast, the contents of storage are slower to access and are preserved when the power is off. The exception is *read-only memory* (ROM), which has the speed of RAM but retains its contents without power; but unlike RAM and storage devices, ROM's contents are fixed and cannot be changed.

The CPU and RAM typically are placed on the same *board* or *card*, which is simply a rigid structure into which silicon chips are placed, along with conducting material that allows electrical signals to flow between the chips. A signal-conducting path is called a *bus*. Buses exist between cards, between chips on a card, and within the chips themselves. The width of a bus is simply the number of individual bits (one bit per "wire") that can be transmitted at the same time; the capacity of a bus is determined by its width combined with its clock speed, which isn't necessarily the same speed as the CPU clock speed.

Common storage devices use magnetic media, either as tapes or disks. Disks can be either fixed or removable; early removable magnetic disks were flexible and so were called *floppy disks*, and the name has been retained even though current "floppies" are enclosed in a rigid case. Large capacity magnetic disk storage devices are commonly called *hard drives* because the disks themselves are hard, not flexible, and they have a motor (drive) that spins them. Although floppies are removable from their drives, hard disks are not; if a hard disk is removable, as with some portable laptop machines, both the magnetic disk and its drive are removed as a single enclosed unit.

Magnetic tapes come in a wide variety of sizes and are relatively inexpensive, but they share the characteristic of

TABLE 18-1 Characteristics of Common Storage and Memory Devices

Storage/Memory Device	Typical Storage Capacity in Megabytes	Typical Maximum Data Transfer Rates (Reading) in Megabytes/sec
Cache memory	0.06-0.5	1000-8000
RAM	128-1024	400-2000
Floppy disk	1.44	0.05-0.5
USB flash memory stick	16-512	0.8-1.5
CD-ROM	650-680	2-8
DVD	4700-17,000	1-16
Hard disk	10,000-200,000	5-200
Magnetic tape	1000-500,000	0.5-8

requiring a spool of magnetic-coated material to be wound past a read-write head. As a result, they tend to be relatively slow, and have become relegated to use as storage for routine copies done at periodic intervals *(backups)*.

Optical disks are storage media onto which digital data are written and from which they are read using laser light; these include *compact disks* (CDs) of both read-only (CD-ROM) and read-write (CD-RW) varieties, and *digital versatile disks* (DVDs). Generally slower than magnetic hard drives, they have the advantages of being removable, much faster than magnetic tape, and capable of containing enough storage to be useful for backup and distribution of large quantities of digital data.

Storage and memory devices have a broad range of storage capacity and speed as listed in Table 18-1. The combination of speed and capacity dictates when and where each of these devices is most useful (Figure 18-1).

Any device connected to the computer but not essential for its basic operation can be called a *peripheral device.* Peripherals also may be regarded as those devices connected to the computer via a cable. With the possible exception of the hard drive that contains the operating system, most storage devices can be regarded as peripherals. Other peripherals include printers, scanners, cameras, and other devices for getting data in or moving data out, typically called *input/output* devices or I/O devices.

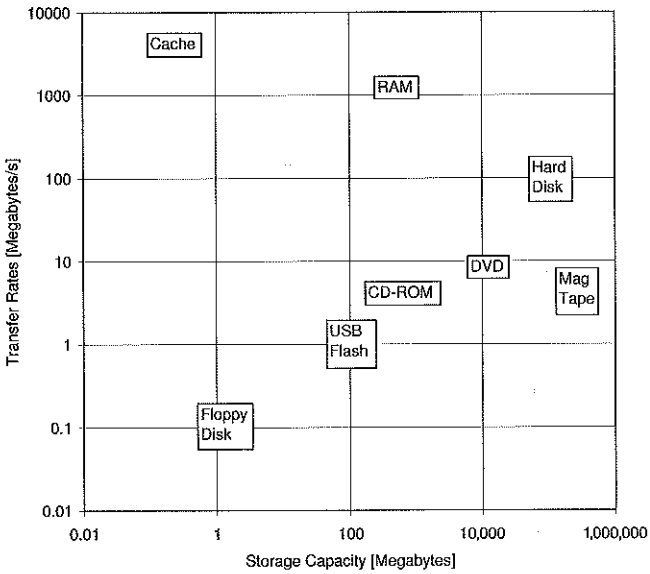

Figure 18-1 Data transfer rate in megabytes/seconds versus storage capacity for selected storage and memory devices.

Rate of Change of Computing Capacity

It could be argued that the field of scientific endeavor that has had the most impact on informatics is computer hardware engineering. Unlike most things in life, the size and expense of computers are rapidly diminishing, and their capacity and speed are rapidly increasing. This dramatic and far-reaching change has been driven primarily by an ever-increasing ability to place large numbers of integrated circuits onto silicon chips. Gordon Moore, one of the founders of the Intel Corp., observed in 1965 that the number of circuits that could be manufactured on a single chip seemed to be doubling approximately every year.[6] This observation has come to be known as "Moore's law" and has been restated and reinterpreted in many ways. For example, some authors have claimed that Moore's law implies that "computer power doubles every 18 months at half the price." Figure 18-2 illustrates the number of transistors on Intel's microprocessors and demonstrates a doubling approximately every 2 years since 1971. This exponential trend toward smaller and more powerful computing devices is seen not just in processors but also in memory, hard disk storage, and communications bandwidth. Although the basic trend continued for approximately 30 years, or 15 doublings, eventually the laws of physics will intervene and the trend will end. Indeed, some authors warn that Moore's law is increasingly an unreliable predictor of future trends.[8] Nevertheless, these changes in power, size, speed, and affordability of computing devices have been nothing short of revolutionary. We can expect this revolution to continue to have a notable impact on healthcare in many ways over the coming years.

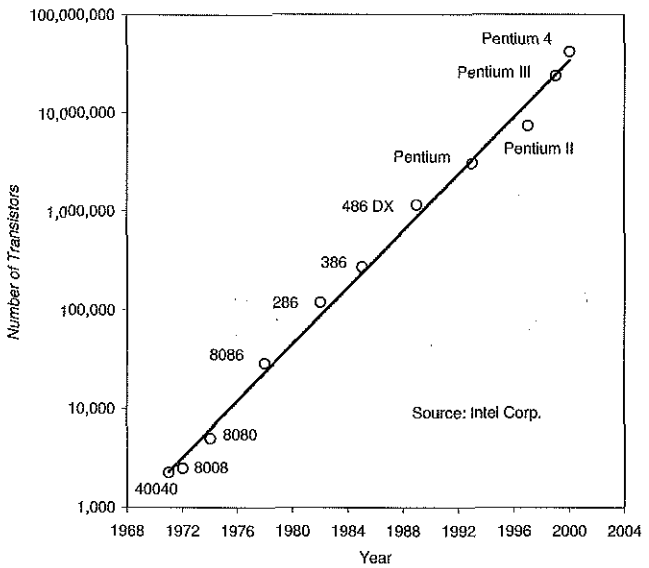

Figure 18-2 Moore's law illustrated: number of transistors per chip doubles every 18 months.

Computer Networks

Communication between computers has become commonplace, and the means of communication is usually some kind of *network*. The basic idea of a network is that a computer can connect to the network and get access, depending on authorization level, to the other computers that have also linked up, and also provide access to itself. Network signals usually travel on electrical or optical cables, although they can also use electromagnetic signals, such as radio waves or infrared light. Networks that connect computers that are all located within a local area, such as one building or perhaps a group of adjacent buildings, are called *local area networks* (LANs). To connect to the network, the computer must have both hardware and software that manages the network connection. The hardware is usually a card, called a *network interface card* (NIC), into which a cable may be connected or, alternatively, to which a wireless transmitter and/or receiver may be connected. A common standard for network hardware is called *ethernet*, which specifies the mechanism for handling the transmission of signals to and/or from the computer's NIC and the transmission medium, such as radio waves, electric pulses in wires, or light pulses in fiberoptic cables. There are also software standards for networking, often called *protocols*. These specify how to divide transmissions into blocks or chunks, how to attach destination addresses, how to signal that a transmission is starting or ending, and so forth. The most widely used set of protocols is called the *Internet protocols*, a nonproprietary suite that includes transmission control protocol (TCP) and Internet protocol (IP), often mentioned together as TCP/IP. These protocols formed the basis for a widely adopted network, called the *Internet*, that grew from what was primarily government and academic use to become virtually ubiquitous. As the Internet grew and became more widely available, additional software protocols were developed for managing the convenient organization and marking of documents that include text, images, and sounds along with the ability to connect from one document to another, even if the other documents are not on the same computer. A document containing such connections is called a *hypertext*. The *hypertext transfer protocol* (HTTP) was specified as a standard for accessing and transmitting hypertext documents that were formatted according to another standard, the *hypertext markup language* (HTML). The set of computers on the Internet that use HTTP to transfer HTML documents is called, collectively, the *Worldwide Web* (WWW). A computer program used for accessing sites or information on a network is termed a *browser*.

Computers may be connected to a LAN but not connected to the Internet. Many businesses, including healthcare organizations, keep their internal networks separate from the wider Internet. An intrainstitutional network is often called an *intranet*, and these are frequently used to connect the institution's information systems.

The phenomenon of the Worldwide Web has resulted in the widespread availability of a vast number of documents and Web pages, easily accessible through search engines such as Google (see www.google.com, accessed May 20, 2004). A search may retrieve a very wide range of quality of documents, ranging from a peer-reviewed journal article to an incoherent rant from a Usenet Newsgroup. Caution is required because the Internet may eliminate, mask, or change the traditional indicators of quality and authoritativeness.

LABORATORY INFORMATION SYSTEMS

Laboratories were the first area of healthcare institutions that adopted computer technology to manage clinical information about the patient. Within the laboratory, chemistry and hematology were the first areas to be supported, followed later by microbiology, blood banking, and anatomical pathology.

One of the first functions supported by laboratory information systems (LISs) was the printing of summary laboratory data for inclusion in the patient's chart. This replaced the labor-intensive and error-prone process of manually writing or typing results on individual slips of paper. Other important intralaboratory functions included assigning accession numbers and tracking specimens and workload. Information system functions have expanded to include virtually every area of laboratory operation.[4]

LIS Modules

Most LISs have different modules that support the natural divisions of the laboratory or groups of those divisions. A *general laboratory module* often supports chemistry and

BOX 18-1 Workflow Steps Necessary to Use a Laboratory Test

Test request	Work list creation
Order entry	Result entry and verification
Collection scheduling	Automated analyzer interface
Label generation	Specimen tracking
Specimen collection	Reflex testing
Specimen transport	Quality assurance
Specimen delivery and accession	Result reporting

hematology, along with immunology, coagulation, urinalysis, and any other parts of the laboratory that tend to perform tests with a fixed numeric result with a reference range. These lab sections and the modules that support them are more likely also to have an automated analyzer to which the LIS is connected via an electronic interface. Laboratory sections that are frequently supported by separate modules include the transfusion service, microbiology, cytopathology, and surgical pathology.

Workflow, Entities, Attributes, and Relationships

To understand the way laboratory information systems work, it is helpful to think about laboratory workflow and the kinds of information required at each step. Box 18-1 lists a set of workflow steps usually followed by a laboratory test.

Different data elements are required at each step in the workflow. The *test request* originates with the ordering physician or provider, and may be hand written, spoken, or entered electronically. *Order entry* signifies the point at which the test request becomes properly specified according to the information system's data structures. At this step, identifiers are required for the patient, the ordering provider, and the test to be performed. Tests must be identified according to the list of tests known to the system, and can sometimes also be modified to include specific timing, pretest preparation, and other variables. *Accession* refers to the point at which a specimen becomes known to the information system, and usually corresponds closely with the delivery of the specimen to the laboratory. A unique accession number is assigned, allowing the information system to track the specimen and correlate it with the order.

Information systems are often described in terms of the *entities* about which they manage information, the *attributes* that describe those entities, and the *relationships* between the entities. This approach to modeling the information is called *entity-relationship modeling* or *E-R modeling*. Patients, providers, specimens, and orders are examples of *entities*, and medical record number, provider identifier, accession number, and order number are all examples of *attributes*. The *relationship* between these entities is represented by a data structure that includes a particular patient identification (ID), provider ID, order ID, and accession number. To design the information system, data analysts often begin by identifying all the *entities* about which we will require information, the *attributes* or data elements that detail the specifics about these entities, and the *relationships* that connect different entities to each other.

Data Standards and Encoding

Whenever information must be shared between two different information systems, a common method of identifying entities must also be shared. The broader the necessity for sharing, the more universal the identifiers have to be. For this reason, numerous standards have been developed to help identify and share information about healthcare information entities such as laboratory tests, images, diagnoses, and procedures.

In the United States, the 1996 HIPAA legislation (the Health Insurance Portability and Accountability Act) resulted in the designation of six required code sets for billing and reimbursement. These are listed in Table 18-2.

The code sets required for billing and reimbursement are capable of representing only a limited amount of information about the health or healthcare of a patient. These limitations are a result of the intended use of the codes (i.e., determining an appropriate dollar figure to attach to a particular procedure or condition). Researchers have evaluated the ability of these code sets to represent the level of detail required for conducting studies of the outcomes of healthcare or enabling computer-based decision support, and have found them to be notably less detailed than required. As a result, a second group of standards was designated by HIPAA as those that support patient medical record information (PMRI). These PMRI standards are not mandated by the government but are recommended for supporting the voluntary movement toward adoption by clinical information systems and healthcare organizations. The most important PMRI standards for clinical laboratories are the Systematized Nomenclature of Medicine—Clinical Terms (SNOMED CT[7]) and Laboratory Logical Observation Identifiers, Names, and Codes (Lab LOINC[9]).

SNOMED CT

SNOMED CT is a clinical terminology, used to code information about health and the care of individuals and populations. At its most basic level, it contains a set of codes, each representing a different concept. For example, "acute appendicitis" is one concept, and "appendicitis" is another concept, and each has its own code. These concept codes are connected to each other in a hierarchy (represented in a data table), with more general concepts such as "appendicitis" located above more specific concepts such as "acute appendicitis." In addition to this hierarchy, concepts are also connected to each other via *attributes* that specify defining characteristics. For example, "appendicitis" may be

TABLE 18-2 U.S. Code Sets for Billing and Reimbursement

Code Set	Purpose
ICD-9-CM vol 1&2: International Classification of Diseases, 9th Edition, Clinical Modification, Volumes 1 and 2	Diseases, injuries, impairments, other health-related problems and their manifestations; causes of injury, disease, impairment, or other health-related problems
ICD-9-CM vol 3: International Classification of Diseases, 9th Edition, Clinical Modification, Volume 3 Procedures	Hospital inpatients: prevention, diagnosis, treatment, management
NDC: National Drug Codes	Retail pharmacies: drugs, biologicals
CDT-2: Code on Dental Procedures and Nomenclature	Dental services
CPT-4: Current Procedural Terminology plus HCPCS: Health Care Financing Administration Common Procedure Coding System	Physician services, physical and occupational therapy services, radiological procedures, clinical laboratory tests, other medical diagnostic procedures, hearing and vision services, transportation services including ambulance
HCPCS	Medical supplies, orthotic and prosthetic devices, durable medical equipment

linked via the attribute *site* to the anatomical concept "appendix."

The scope of SNOMED CT is very broad, encompassing human and veterinary medicine, nursing, dentistry, allied health professions, and population-based health concepts. It includes codes for diagnoses, procedures, findings, drugs, anatomy, organisms, causes of disease, and social aspects of health. Included in SNOMED's procedure hierarchy is a very complete list of laboratory tests and test categories. To provide smooth integration, there is a file that links these SNOMED CT codes to related Lab LOINC codes.

Lab LOINC

Lab LOINC is a set of codes designed to represent laboratory test names. These codes are intended to be used for reporting the values of tests when there is a necessity to provide laboratory test information in electronic form to any information system that does not use the same test identifiers as the originating laboratory information system. This could include transmitting test results from one LIS to another within an institution: (e.g., in providing chemistry results to an anatomical pathology system); or to a more central hospital information system; or beyond to any number of more remote systems. Sharing information in this way requires a common understanding of exactly what test was performed and how it is being reported, and the Lab LOINC codes enable the appropriate level of detail to accomplish this purpose.

The meaning of each code is specified using a six-part name. The six parts are *component* (what is measured), *kind of property* (e.g., concentration versus titer), *time aspect* (single point in time versus timed collection), *system (specimen) type, type of scale* (e.g., quantitative, ordinal, and nominal), and *method*. For example, the LOINC name for a rickettsial antibody titer done on serum by complement fixation and reported as a quantitative number is "Rickettsia sp AB|Titer|PT|Serum|QN|CF," and its code is 5306-6. Table 18-3 lists several LOINC codes, along with a corresponding SNOMED code. The meaning of each part of the LOINC name is illustrated in Figure 18-3.

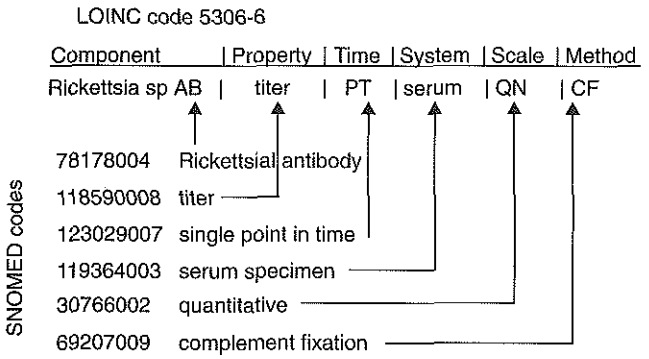

Figure 18-3 Parts of LOINC names, with SNOMED codes.

LOINC-SNOMED Integration

The relationship between the SNOMED hierarchy and the LOINC codes can be illustrated as in Figure 18-3, where more general SNOMED concepts, such as "rickettsial serological test," would be connected to several more specific rickettsial serological tests that would be reported using Lab LOINC codes.

In addition, SNOMED and LOINC are linked through a SNOMED code for each of the LOINC name parts, as illustrated in Figure 18-4. The SNOMED hierarchies for these codes will enable software systems to automatically compute that a complement fixation test for Rickettsia is a subtype of

TABLE 18-3 SNOMED-LOINC Correlation Example

SNOMED Code	LOINC Code	Concept name
17652006		**Serological Test for *Rickettsia rickettsii***
	29705-1	RICKETTSIA RICKETTSII AB|TITR|PT|SER|QN|IF
	29706-9	RICKETTSIA RICKETTSII AB|ACNC|PT|SER|ORD|IF
	29737-4	RICKETTSIA RICKETTSII AB|TITR|PT|SER|QN|
	5307-4	RICKETTSIA RICKETTSII AB.IGG|TITR|PT|SER|QN|IF
	8003-6	RICKETTSIA RICKETTSII AB.IGG|ACNC|PT|SER|QN|
	18430-9	RICKETTSIA RICKETTSII AB.IGM|ACNC|PT|CSF|QN|
	22483-2	RICKETTSIA RICKETTSII AB.IGM|TITR|PT|SER|QN|
	5308-2	RICKETTSIA RICKETTSII AB.IGM|TITR|PT|SER|QN|IF
	8004-4	RICKETTSIA RICKETTSII AB.IGM|ACNC|PT|SER|QN|
117992009		**Rickettsia (Proteus OX19) Antibody Assay**
	21489-0	RICKETTSIA (PROTEUS OX19) AB|TITR|PT|SER|QN|LA
	22468-3	RICKETTSIA (PROTEUS OX19) AB|ACNC|PT|SER|ORD|
	22469-1	RICKETTSIA (PROTEUS OX19) AB|TITR|PT|SER|QN|
	31593-7	RICKETTSIA (PROTEUS OX19) AB|ACNC|PT|SER|QN|
	5303-3	RICKETTSIA (PROTEUS OX19) AB|ACNC|PT|SER|ORD|LA

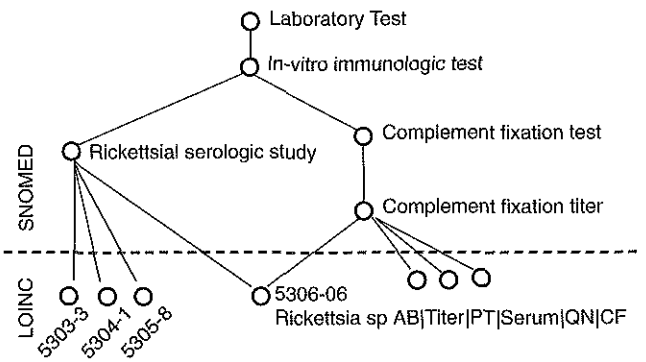

Figure 18-4 LOINC-SNOMED hierarchy integration.

a complement fixation test for a microbial antibody, because the code for Rickettsia species antibody is in the hierarchy for microbial antibodies.

Table 18-3 lists SNOMED codes for rickettsial serologies, along with some of the more specific LOINC codes that are subtypes of these concepts. The LOINC concepts differ based on whether they measure a titer (TITR) or an arbitrary concentration (ACNC); whether they are measuring the antibody in the serum (SER) or another specimen, such as the cerebrospinal fluid (CSF); whether the reported value is quantitative (QN) or ordinal (ORD); and whether the method is specified, such as immunofixation (IF) or latex agglutination (LA). Note that the words "serological test" are intended to mean testing for the antibody to the organism, regardless of the specimen (serum, CSF, or other). Thus in this example the SNOMED code specifies only the "component" part of the LOINC code and leaves the other five LOINC fields unspecified. In Figure 18-4 the SNOMED concept "complement fixation titer" specifies only the SCALE and PROPERTY and leaves the other four LOINC fields unspecified.

Life Cycle of Information Systems

Information systems can be understood as having a life cycle analogous to living organisms. Understanding where a system is in its life cycle can provide insight into the most appropriate steps to be taken to properly manage the system. Major phases in the life cycle of information systems include a definition or specification phase, an acquisition or development phase, an implementation and deployment phase, an operation and maintenance phase, and a disposition phase.

Definition and/or Specification

The earliest phase of an information system cycle, the definition phase involves recognition of and explicit justification of the requirement for the system, including detailed analysis of how information is presently being handled and how the new system would change and improve upon current practices. Success of later phases depends on the care with which the definition and specification are carried out.

Acquisition and/or Development

Although it is possible for a laboratory to develop its own LIS, most healthcare institutions lack the expertise to do this, and when facing a build-or-buy decision they usually come down on the side of "buy." The identification of suitable commercial vendors usually begins with a request for information (RFI), providing basic information about the vendor and its software offerings, followed by a request for proposal (RFP), which asks the vendors to respond to a set of more

detailed functional questions designed to assist the laboratory in determining whether, and how well, the vendor's offerings can meet the laboratory's requirements. A convenient source listing vendors is a survey of LIS companies published each fall by *CAP Today* (see www.cap.org, accessed May 20, 2004).

Implementation and Deployment

Once LIS software has been selected, the next step is implementation, a process that usually requires many weeks of concerted effort on the part of both the vendor and the laboratory. The success of an LIS depends directly on how well it is configured to fit the requirements of the laboratory. Transition from a prior information system usually requires extensive training or retraining of laboratory personnel and revision of standard operating procedures. Most implementations also encounter unexpected problems that require additional time and resources.

Most large laboratories will require 12 to 18 months at a minimum, and frequently more, to progress through the first three phases of definition, acquisition, and implementation.

Operation and Maintenance

Once in place, an LIS must be supported and maintained. Software modules and operating systems may have to be upgraded and synchronized. Interfaces to laboratory instruments and communication links with clinical systems also frequently require upgrading and support. Although one might hope that an LIS could evolve gracefully and not require replacement, in practice all information systems inevitably become obsolete, and a new system life cycle begins.

Disposition

Although most of the work to replace an obsolete system involves the definition, acquisition, and implementation of a new system, the disposition of the old system also has to be considered. In particular, data preservation and migration should be carefully evaluated.

Regulatory Issues

In the United States, federal regulations apply to any device, including computers and information systems that directly impact the patient or the process of production of devices and substances that come into contact with the patient. As a result, computer software that is used in the collection, tracking, and processing of blood products is subject to Food and Drug Administration (FDA) preapproval and ongoing inspection. These regulations require careful documentation of the development of the software, and rigorous testing and validation at the time of implementation and again at the time of any upgrade or change.[1]

General LIS applications, outside blood collection or transfusion services, are not subject to FDA regulations, but many laboratories voluntarily subject their LIS to inspection and accreditation. The College of American Pathologists (CAP) inspection and accreditation checklists for laboratory computer software focus on documentation of practices that ensure the safe and reliable operation of the system, such as regular backup of data, validation of system function following software upgrades, and regular testing of the correctness of transmitted or printed laboratory results.

Security and Confidentiality

The administrative simplification provisions of HIPAA were written with the understanding that improvements in safeguards of electronic health information must go hand in hand with increasing detail and sharing of such electronic data. The traditional paper record was inaccessible to all but the individual having possession of the physical record; this created problems when the record was lost, or was necessary at more than one location, but it also provided a natural limit on the accessibility to unauthorized parties. As information becomes available in electronic form, patients have an interest in improved security and confidentiality of their health records.

Security generally refers to the provisions for ensuring that electronic data are prevented from unintentional destruction, loss, alteration, or disclosure. *Confidentiality* refers to the expectation that information about a patient should remain within the patient's control, should be disclosed only to authorized individuals, and should not be used for purposes the patient does not approve.

Achieving a balance between access and security is not simple. In a hospital, numerous individuals have a need to handle patient data; too strict limits on access to data can harm patients by preventing healthcare workers from providing the best care. On the other hand, lax security leaves patients and the institution in danger of harm from unauthorized access to data.

Measures necessary for ensuring security include careful management of access to computer systems, monitoring and tracking access, and judicious application of penalties for violation of security policy. Each user should be required to be identified to the system, and access should depend on a password or other secure mechanism that prevents unauthorized access. Access to patient data, and particularly changes to data, should be automatically logged according to user, date and time, and action taken. These logs are called *audit trails,* an important tool for monitoring system security. When employees inappropriately access patient data for which they have no responsibility, penalties up to and including dismissal should be known and applied when necessary.

PATHOLOGY INFORMATICS RESOURCES

A number of annual meetings are available for laboratory medicine professionals interested in informatics. These include:

- Automated Information Management in the Clinical Laboratory (AIMCL)

- Advancing Pathology Informatics, Imaging, and the Internet (APIII): see apiii.upmc.edu
- Lab InfoTech Summit: see https://www.labinfotech.org/

CHAPTER 19

Quality Management

James O. Westgard, Ph.D.,
and George G. Klee, M.D., Ph.D.

The principles of quality management, assurance, and control have become the foundation by which clinical laboratories are managed and operated. This chapter begins with a discussion of the fundamentals of total quality management followed by discussions of (1) total quality management of the clinical laboratory, (2) laboratory error and the Six Sigma process, (3) elements of a quality assurance program, (4) control of preanalytical variables, (5) control of analytical variables, (6) control of analytical quality using stable control materials, (7) control of analytical quality using patient data, (8) external quality assessment and proficiency testing programs, and (9) identifying the sources of analytical errors. We conclude the chapter with a discussion on quality initiatives, including the ISO 9000 certification process.

FUNDAMENTALS OF TOTAL QUALITY MANAGEMENT

Quality systems in healthcare organizations continue to evolve* with numerous sources of information on quality available on the Internet.[26] Public and private pressures to contain costs are now accompanied by pressures to improve quality. The seemingly contradictory pressures for both cost reduction and quality improvement (QI) require that healthcare organizations adopt new systems for managing quality. When faced with these same pressures, other industries implemented "total quality management," or TQM.[101] TQM may also be referred to as total quality control (QC), total quality leadership, continuous quality improvement, or quality management science, or more generally as industrial quality management. TQM provides both a management *philosophy* for organizational development and a management *process* for improving the quality of all aspects of work. Many healthcare organizations have adopted the concepts and principles of TQM.[4]

*References 37, 39, 65, 67, 74, 87, 99, 104, 111.

Fundamental Concepts

In this chapter, quality is defined as conformance to the requirements of users or customers. More directly, quality refers to the satisfaction of the needs and expectations of users or customers. The focus on users and customers is important, particularly in service industries such as healthcare. The users of healthcare laboratories are often the nurses and physicians; their customers are the patients and other parties who pay the bills.

Cost must be understood in the context of quality. If quality means conformance to requirements, then "quality costs" must be understood in terms of "costs of conformance" and "costs of nonconformance," as illustrated in Figure 19-1. In industrial terms, costs of conformance are divided into prevention costs and appraisal costs. Costs of nonconformance consist of internal and external failure costs. For a laboratory testing process, calibration is a good example of a cost incurred to prevent problems. Likewise, quality control is a cost for appraising performance, a repeat run is an internal failure cost for poor analytical performance, and repeat requests for tests because of poor analytical quality are an external failure cost.

This understanding of quality and cost leads to a new perspective on the relationship between them. Improvements in quality can lead to reductions in cost. For example, with better analytical quality, a laboratory can eliminate repeat runs and repeat requests for tests. This repeat work is "waste." If quality were improved, waste would be reduced, which in turn would reduce cost. The father of this fundamental concept was the late W. Edwards Deming, who developed and internationally promulgated the idea that quality improvement reduces waste and leads to improved

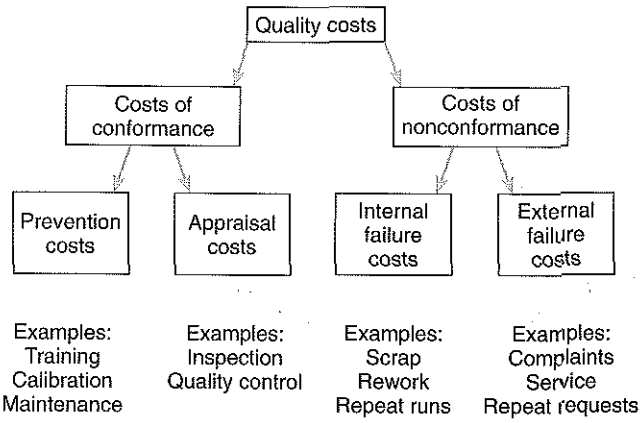

Figure 19-1 The cost of quality in terms of the costs of conformance and the costs of nonconformance to customer requirements. *(From Westgard JO, Barry PL. Cost-effective quality control: Managing the quality and productivity of analytical processes. Washington DC: AACC Press, 1986.)*

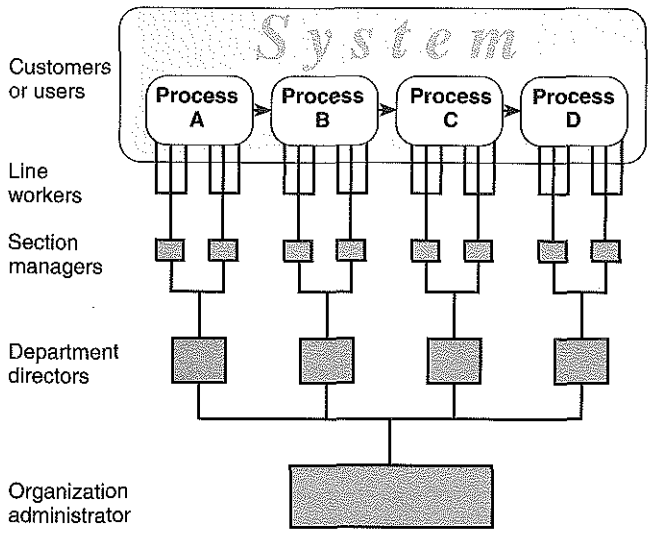

Figure 19-2 TQM view of an organization as a system of processes.

productivity, which in turn reduces costs and provides a competitive advantage.[25] As a result, the organization stays in business and is able to continue providing jobs for its employees.

Fundamental Principles

Quality improvement occurs when problems are eliminated permanently. Problems arise primarily from imperfect processes, not from imperfect people. Industrial experience has shown that 85% of all problems are process problems that are solvable only by managers, with the remaining 15% being problems requiring the action and improvement of performance of individual workers. Thus quality problems are primarily management problems because only management has the power to change work processes.

This emphasis on processes leads to a new view of the organization as a system of processes, as illustrated in Figure 19-2. For example, physicians might view a healthcare organization as a provider of processes for patient examination (A), patient testing (B), patient diagnosis (C), and patient treatment (D). Healthcare administrators might view the activities in terms of processes for admitting patients (A), tracking patient services (B), discharging patients (C), and billing for costs of service (D). Laboratory directors might understand their responsibilities in terms of processes for acquisition of specimens (A), processing of specimens (B), analysis of samples (C), and reporting of test results (D). Laboratory analysts might view their work as processes for acquiring samples (A), analyzing samples (B), performing quality control (C), and releasing patient test results (D). The total system for a healthcare organization involves the interaction of all of these processes and many others.

Given the primary importance of these processes for accomplishing the work of the organization, TQM views the organization as a support structure rather than as a command structure. As a support structure, the most immediate processes required for the delivery of services are those of the frontline employees. Upper management's role is to support the frontline employees and to *empower* them to identify and solve problems in their own work processes.

The importance of empowerment is easily understood if a problem involves processes from two different departments. For example, if a problem occurs that involves the link between process A and process B in Figure 19-2, the traditional management structure requires that the problem be passed up from the line workers to a section manager or supervisor, a department director, and an organization administrator. The administrator then works back through an equal number of intermediaries in the other department. Direct involvement of line workers and their managers should provide more immediate resolution of the problem.

However, such problem solving requires a carefully structured process to ensure that root causes are identified and proposed solutions are verified. Juran's "project-by-project" quality improvement process[42] provides detailed guidelines that have been widely adopted and integrated into current team problem-solving methodology.[3,4,85] The methodology outlines distinct steps for (1) carefully defining the problem, (2) establishing baseline measures of process performance, (3) identifying root causes of the problem, (4) identifying a remedy for the problem, (5) verifying that the remedy actually works, (6) "standardizing" or generalizing the solution for routine implementation of an improved process, and (7) establishing ongoing measures for monitoring and controlling the process.

The quality improvement "project team" provides a new flexible organization unit. A project team is a group of employees appointed by management to solve a specific problem that has been identified by management or staff. The team comprises members from any department and from any level of the organization and includes anyone who

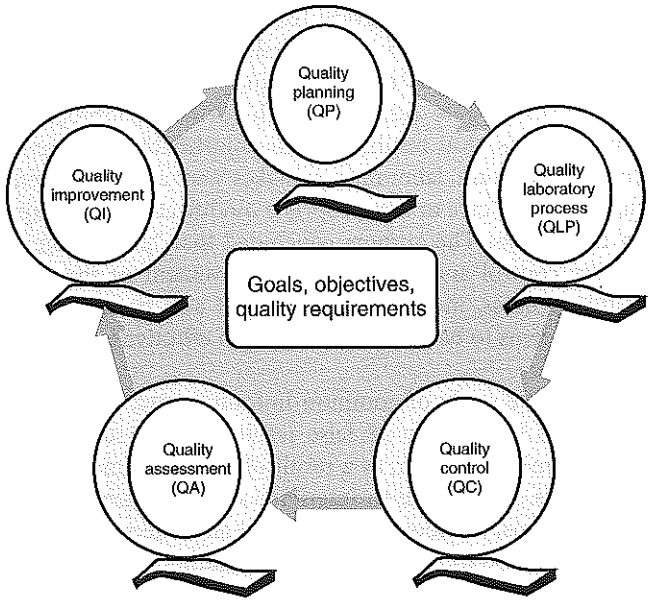

Figure 19-3 TQM framework for managing quality in a healthcare laboratory. *(From Westgard JO, Burnett RW, Bowers GN. Quality management science in clinical chemistry: A dynamic framework for continuous improvement of quality. Clin Chem 1990;36:1712-6.)*

is necessary to understand the problem and identify the solution. Management initiates the project, and the team is empowered and supported to identify the root cause and verify a solution; the management then becomes involved in replanning the process (i.e., planning the implementation of changes in a laboratory process, defining and standardizing the improved process, and establishing appropriate measures for ongoing evaluation and control of the process).[112]

TOTAL QUALITY MANAGEMENT OF THE CLINICAL LABORATORY

The principles and concepts of TQM have been formalized into a quality management process, as illustrated in Figure 19-3. The traditional framework for managing quality in a healthcare laboratory has emphasized the establishment of quality laboratory processes (QLPs), QC, and quality assessment (QA). A QLP includes analytical processes and the general policies, practices, and procedures that define how all aspects of the work get done. QC emphasizes statistical control procedures but also includes nonstatistical check procedures, such as linearity checks, reagent and standard checks, and temperature monitors. QA, as currently applied, is primarily concerned with broader measures and monitors of laboratory performance, such as turnaround time, specimen identification, patient identification, and test utility. Quality "assessment" is the proper name for these activities rather than quality "assurance." Measuring performance does not by itself improve performance and often does not detect problems in time to prevent harmful effects. Quality assurance requires either that causes of problems be identified through QI and eliminated through quality planning (QP) or that QC be able to detect the problems early enough to prevent their consequences.

To provide a fully developed system and framework for managing quality, the QI and QP components must be established.[65,67,111] QI provides a structured problem-solving process for identifying the root cause of a problem and also for identifying a remedy for the problem. QP is necessary to (1) standardize the remedy, (2) establish measures for monitoring performance, (3) ensure that the performance achieved satisfies quality requirements, and (4) document the new QLP. The new process is then implemented through QLP, measured and monitored through QC and QA, improved through QI, and replanned through QP. These five components, working together in a feedback loop, illustrate how continuous QI is accomplished and how quality assurance is built into laboratory processes.

The "five-Q" framework also defines how quality can be managed objectively using the "scientific method" or the *PDCA cycle* (**p**lan, **d**o, **c**heck, **a**ct). QP provides the planning step, QLP establishes standard processes for doing things, QC and QA provide measures for checking how well things are done, and QI provides a mechanism for acting on those measures. The methodology that we naturally apply in scientific experiments should also be the basis for objective management decisions.

Objectivity, however, is dependent on our having quantitative quality requirements for evaluating the performance of existing processes and for planning the performance of new processes.[114] Laboratories must define their service goals and objectives and establish clinical and analytical quality requirements for testing processes. Without such quality goals, there is no objective way to determine whether acceptable quality is being achieved, to identify processes that have to be improved, or to plan or design new processes that ensure that a specified level of quality will be attained.

Quality goals cannot be set on an absolute basis. They vary from laboratory to laboratory, depending on the medical missions of the healthcare facilities and professional interests of the physicians using the laboratory tests. Quality goals must also be considered in relation to cost. A goal of achieving the highest possible quality is not appropriate or practical when costs are being curtailed. In establishing quality goals, it is therefore more realistic to specify the quality that is necessary or adequate for the medical applications of the laboratory test results to be produced.

The balance of this chapter focuses primarily on analytical quality and the procedures by which it is monitored. Goals for analytical quality are established in the same way that they are established for purposes of method evaluation (see Chapter 14). The philosophy is to define an "allowable analytical error" based on "medical usefulness" requirements. A "total error" specification is useful because it will permit the calculation of the sizes of random and systematic errors that have to be detected to maintain per-

formance within the allowable error limit (see Chapters 14 and 17).[71] Medical decision concentrations (i.e., the concentrations at which medical interpretation of laboratory test results is particularly critical) are important in establishing the analytical concentrations at which analytical performance has to be most carefully monitored. Thus analytical goals can be established by specifying the allowable analytical error and the critical medical decision concentration. Method evaluation is only the first step in validating that analytical performance satisfies those goals. Quality control procedures should provide for the continuing verification that those goals are being achieved during routine service.

LABORATORY ERROR AND THE SIX SIGMA PROCESS

A study by the Institute of Medicine has found that more than 1 million preventable injuries and 44,000 to 98,000 preventable deaths occur annually in the United States.[49,53] Further publications have offered suggestions for minimizing medical errors in general.[5,24,53-55,82] The magnitude of laboratory errors and the use of the Six Sigma process in controlling them are discussed in the following sections.

Number of Errors Made in the Clinical Laboratory

In 1989, a study was conducted in which 363 incidents captured by a laboratory's quality assurance program in a hospital were evaluated.[78] Incidents included those in which (1) physicians' orders for laboratory tests were missed or incorrectly interpreted, (2) patients were not properly prepared for testing or were incorrectly identified, (3) specimens were collected in the wrong containers or mislabeled or mishandled, (4) the analysis was incorrect, (5) data were entered improperly, and (6) results were delayed, not available, or incomplete, or they conflicted with clinical expectations.

After evaluation of the data, the authors found no effect on patient care for 233 patients; 78 patients were not harmed, but were subjected to an unnecessary procedure not associated with increased patient risk; and 25 patients were not harmed, but were subjected to an additional risk of inappropriate care. Of the total number, preanalytical mistakes accounted for 218 (45.5%), analytical for 35 (7.3%), and postanalytical, 226 (47.2%). Nonlaboratory personnel were responsible for 28.6% of the mistakes. An average of 37.5 patients per 100,000 treated were placed at increased risk because of mistakes in the testing process.

In a 1997 study, Witte and colleagues investigated the rates of error within the analytical component and found that widely discrepant values were rare, occurring in only 98 of 219,353 analyses.[130] When these results were converted into a standard metric of errors per million episodes, an error rate of 447 ppm was calculated.[5] In another 1997 study, Plebani and Carraro identified 189 mistakes from a total of 40,490 analyses, a relative frequency of 0.47% (4667 ppm). The distribution of mistakes was 68.2% preanalytical (3183 ppm), 13.3 % analytical (620 ppm), and 18.5% postanalytical (863 ppm).[72] Most of the laboratory mistakes did not affect patients' outcomes, but in 37 patients, laboratory mistakes were associated with further inappropriate investigations, thus resulting in an unjustifiable increase in costs. In addition, laboratory mistakes were associated with inappropriate care or inappropriate modification of therapy in 12 patients. The authors concluded that "promotion of quality control and continuous improvement of the total testing process, including preanalytical and postanalytical phases, seems to be a prerequisite for an effective laboratory service."[72]

In a 2002 study of common immunoassays, Ismail and colleagues found only 28 false results from 5310 patients (5273 ppm).[40] However, as a result of incorrect immunoassay results attributable to interference, one patient had 15 consultations, 77 laboratory tests, and an unnecessary pituitary computed tomography scan. The authors stress (1) the necessity for good communication between clinician and laboratory personnel, (2) the importance of the clinical context, and (3) the necessity for use of multiple methods for identifying erroneous test results—a necessity for a rigorous and robust quality system. Heterophilic antibody blocking studies were most effective in identifying interference, but in 21% of patients with false results, dilution studies or alternative assays were necessary to identify the problem. In a similar study, Marks enlisted participation from 74 laboratories from a broad international spectrum of settings and found that 6% of analyses gave false-positive results and, as in the Ismail study, found that use of a heterophilic blocking reagent corrected approximately one third of these.[58] Further evaluation of the data showed no consistent pattern for false results: errors were distributed across donors, laboratories, and systems of analysis. In reviewing the data from these last two studies, Leape suggested setting up a system that would ensure that every result was given a rigorous review before being reported.[53]

In 2002, Bonini and Plebani conducted several MEDLINE studies of laboratory medical errors and found a large heterogeneity in study design and quality and a lack of a shared definition of "laboratory error."[6] However, even with these limitations, they concluded that most such errors occur in the preanalytical phase and suggested that these could be reduced by the implementation of a more rigorous methodology for error detection and classification and the adoption of proper technologies for error reduction. Thus current QA programs that monitor only the analytical phase of the total process have to be expanded to include both the preanalytical (see Chapter 17) and postanalytical phases (www.westgard.com/essay34). By expanded monitoring, the total process would then be managed so as to reduce or eliminate all defects within the process.[72]

Six Sigma Principles and Metrics

Six Sigma[36] is an evolution in quality management that is being widely implemented in business and industry in the

new millennium.[76] Six Sigma metrics are being adopted as the universal measure of quality to be applied to their processes and the processes of their suppliers. The principles of Six Sigma go back to Motorola's approach to TQM in the early 1990s and the performance goal that *"6 sigmas or 6 standard deviations of process variation should fit within the tolerance limits for the process"*; hence, the name Six Sigma (http://mu.motorola.com/). For this development, Motorola won the Malcolm Baldridge Quality award in 1988.

Six Sigma provides a more quantitative framework for evaluating process performance and more objective evidence for process improvement. The goal for process performance is illustrated in Figure 19-4, which shows an error distribution of a measurement procedure that fits acceptably within the tolerance specifications or quality requirements for that measurement. Any process can be evaluated in terms of a sigma metric that describes how many sigmas fit within the tolerance limits. The power of the sigma metric comes from having a universal measure of process performance that facilitates benchmarking across industries.

There are two methodologies for assessing process performance in terms of a sigma metric (Figure 19-5). One approach is to measure outcomes by inspection. The other approach is to measure variation and predict process performance. For processes in which poor outcomes can be counted as errors or defects, the defects are expressed as defects per million (DPM), then converted to a sigma metric using a standard table available in any Six Sigma text.[36] At this time, when healthcare outcomes and reducing medical errors are of great interest, Six Sigma provides a general methodology to describe process outcome on the sigma scale.

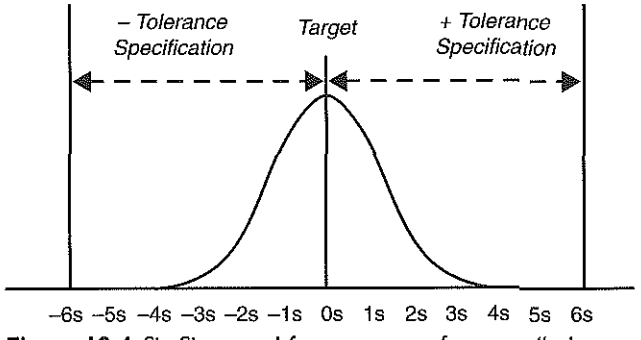

Figure 19-4 Six Sigma goal for process performance "tolerance specification" represents the quality requirement.

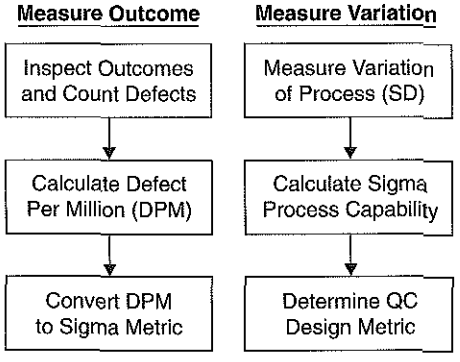

Figure 19-5 Six Sigma methodologies for measuring process performance. Method of measuring process variation is applicable to analytical testing processes.

To illustrate this assessment, consider the well-known problem with a certain brand of tires on a certain brand of sport utility vehicle (SUV) in the United States. A poor outcome, or defect, is defined as a tire blowout that causes an accident. Using data available to the public, there were 2000 accidents in vehicles equipped with these tires, leading to a recall of 6,000,000 tires. The defect rate is then estimated at 333 DPM (2000/6,000,000), or 0.033%, which corresponds to a sigma of 4.9 using a DPM-to-sigma conversion table. For comparison or benchmarking purposes, airline baggage handling has been described as 4.15 sigma performance and airline safety (0.43 deaths per million passenger miles) as better than Six Sigma performance. A defect rate of 0.033% would be considered excellent in any healthcare organization, where error rates from 1% to 5% are often considered acceptable.[5] A 5.0% error rate corresponds to 3.15 sigma performance and a 1.0% error rate corresponds to 3.85 sigma. Six Sigma shows that the goal should be error rates of 0.1% (4.6 sigma) to 0.01% (5.2 sigma) and ultimately 0.001% (5.8 sigma).

The first application describing sigma metrics in a healthcare laboratory was published by Nevalainen[68] in the year 2000. This application focused on preanalytical and postanalytical processes. Order accuracy, for example, was observed to have an error rate of 1.8%, or 18,000 DPM, which corresponds to 3.6 sigma performance. Hematology specimen acceptability showed a 0.38% error rate, or 3800 DPM, which is 4.15 sigma performance. The best performance observed was for the error rate in laboratory reports, which was only 0.0477%, or 477 DPM, or 4.80 sigma performance. The worst performance was therapeutic drug monitoring timing errors of 24.4%, or 244,000 DPM, which is 2.20 sigma performance.

Of the studies discussed in the section above, the error rates computed in DPM can be converted to sigma metrics. For example, for the Ross-Boone study,[78] the computed DPM corresponds to a 3.3 sigma long-term performance. For the Plebani study,[72] a DPM of 620 DPM corresponds to 3.2 sigma long-term performance. In the Ismail study,[40] a DPM of 5273 corresponds to 2.6 sigma long-term performance. On average, this indicates about 3.03 sigma long-term performance.

The application of sigma metrics for assessing analytical performance depends on measuring process variation and determining "process capability" in sigma units.[83,94,103] This approach makes use of the information on precision and accuracy that laboratories acquire initially during method validation studies and have available on a continuing basis from internal and external quality control. An important

aspect of this methodology is that the capability, or predictive performance, of the process must be ensured by proper quality control, therefore the ease of assessment comes with the responsibility to design and implement QC procedures that will detect medically important errors.

To apply this methodology, the tolerance limits are taken from performance criteria for external quality assessment programs or regulatory requirements (such as the U.S. Clinical Laboratory Improvement Amendment [CLIA] criteria for acceptable performance in proficiency testing); process variation and bias can be estimated from method validation experiments, peer-comparison data, proficiency testing results, and routine QC data. For laboratory measurements, it is straightforward to calculate the sigma performance of a method from the imprecision: standard deviation (SD) or coefficient of variation (CV) and inaccuracy (bias) observed for a method and the quality requirement (allowable total error, TE_a) for the test [Sigma = (TE_a – bias)/SD]. For a cholesterol test with a CLIA criterion of 10.0%, method bias of 1.0%, and method CV of 2.0%, the sigma metric is 4.5 [10.0 – 1.0/2.0]. If the method had a CV of 3.0% and a bias of 3.0% (the maximum allowable figures according to the National Cholesterol Education Program [NCEP] guidelines), the sigma metric is 2.33. Sigma metrics from 6.0 to 3.0 represent the range from "best case" to "worst case." Methods with Six Sigma performance are considered "world class"; methods with sigma performance less than 3 are not considered acceptable for production.

Those conclusions can be readily understood by considering the amount of quality control that is necessary for measurement processes having different performance metrics. Figure 19-6 shows a "power function graph" that describes the probability for rejecting an analytical run on the y-axis versus the size of the systematic error that has to be detected on the x-axis. The bold vertical lines correspond to methods having 3, 4, 5, and 6 sigma performance (left to right). The different lines or power curves correspond to the control rules and number of control measurements given in the key at the right (top to bottom). These different QC procedures have different sensitivities or capabilities for detecting analytical errors. Practical goals are to achieve a probability of error detection of 0.90 (i.e., a 90% chance of detecting the critical-sized systematic error, while keeping the probability of false rejection at 0.05 or less [i.e., 5% or lower chance of false alarms]). That is easy to accomplish for processes with 5 to 6 sigma performance; it requires a more careful selection and increased QC efforts for processes from 4 to 5 sigma; and it becomes very difficult and expensive for processes less than 4 sigma.

Thus the application of Six Sigma principles and metrics is very valuable for all phases of the laboratory testing process. Since the core business of the laboratory is to produce accurate test results, it makes sense to first apply Six Sigma to the analytical processes. That also is the easiest application because there are tolerance limits in the form of acceptability criteria from peer-comparison and proficiency-testing programs, QC data available for estimating method precision, and peer data available for estimating method bias. Laboratories should next expand their efforts to the preanalytical and postanalytical processes, knowing that their core processes are producing the necessary analytical quality.

ELEMENTS OF A QUALITY ASSURANCE PROGRAM

The attainment of quality goals in a clinical laboratory requires a comprehensive quality assurance program. "Quality assurance" is used here to represent practices that are generally recommended for ensuring that desired quality goals are achieved. Quality assurance is a broad spectrum of plans, policies, and procedures that together provide an administrative structure for a laboratory's efforts to achieve quality goals. The term "quality control" is often used to represent those techniques and procedures that monitor performance parameters. Generally, these are quantitative

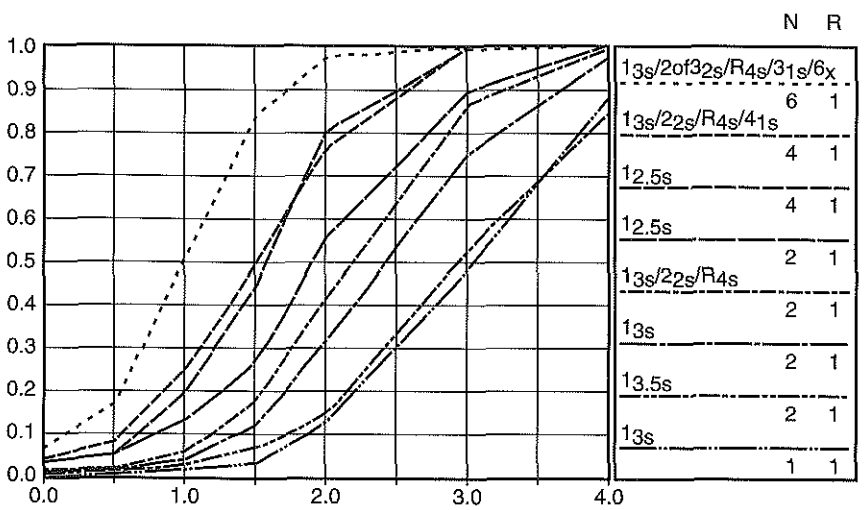

Figure 19-6 Relationship of process performance on the Sigma scale to the performance characteristics of commonly used laboratory QC procedures. Probability for rejection is plotted on the y-axis versus size of systematic error on the x-axis and the Sigma scale on the x-axis. The control rules and number of control measurements are given in the key at the right, where the 8 lines, top to bottom, correspond with the curves on the graph, top to bottom.

techniques that monitor particular sources of errors, estimate the magnitude of the errors, and alert laboratory personnel when there are indications that quality has deteriorated. A quality assurance program involves virtually everything and everybody in the clinical laboratory. An error in any one step during the acquisition, processing, and analysis of a specimen and the reporting of a laboratory test result invalidates the quality of the analysis and causes the laboratory to fall short of its quality goals. There are several essential elements of a quality assurance program.

Commitment

Dedication to quality service must be central and a team effort. Otherwise, quality goals are not likely to be achieved. Quality must be a major consideration in all management decisions because any single decision may compromise other plans and practices for attaining quality goals. A true commitment is required by laboratory directors, managers, and supervisors if the efforts of other laboratory personnel are to be successful.

Facilities and Resources

Laboratories must have the administrative support necessary to provide the quality of services desired. This means having adequate space, equipment, materials, supplies, staffing, supervision, and budgetary resources. These resources provide the basis upon which quality services are developed and maintained.

Technical Competence

High-quality personnel are essential for high-quality services. The educational background and experience of all personnel are important, as is the capability of providing the in-service training that develops and maintains skills. In-service training also is a mechanism for ensuring the competency of laboratory personnel, instilling quality goals, implementing QC procedures, and providing for the continuing development of laboratory personnel, both technically and intellectually.

Technical Procedures

High-quality technical procedures are necessary to provide quality laboratory services. Three groups of procedures are discussed in this chapter:

1. The control of preanalytical conditions or variables, such as test requests, patient preparation, patient identification, specimen acquisition, specimen transport, specimen processing, specimen distribution, preparation of work lists and logs, and maintenance of records (see Chapters 1 and 17).[134]
2. The control of analytical variables, which includes analytical methodology, standardization and calibration procedures, documentation of analytical protocols and procedures, and the monitoring of critical equipment and materials.
3. The monitoring of analytical quality by the use of statistical methods and control charts.

Problem-Solving Mechanism

Although it is a particularly critical element in a quality assurance program, the necessity for a mechanism for problem solving is often underemphasized. Such a mechanism provides the link between the identification of a problem and the implementation of a solution to the problem. It is a "feedback loop" that responds to an error signal by making adjustments to reduce the size of the error or to prevent its recurrence. For problems limited to individual methods or instrument systems, the delegation of responsibility for the systems may provide the corrective mechanism. Specialized trouble-shooting skills need to be developed and improved and preventive maintenance programs instituted. For problems occurring more generally, the in-service training program can be an important part of the mechanism but often requires additional input from a QC specialist or supervisor to initiate the use of this mechanism and to help define its objectives. A different approach to problem solving is the use of quality teams that meet regularly to analyze problems and identify solutions.[85] By involving personnel, quality teams heighten the interest and commitment to quality and also provide a creative feedback mechanism.

The comprehensive nature of quality assurance programs and their missions, goals, and activities have been discussed in greater detail by Eilers.[28] There are also detailed outlines of the elements of cost management for quality assurance[29,44]; detailed recommendations by professional organizations, such as the College of American Pathologists (CAP),[18] the National Committee for Clinical Laboratory Standards (NCCLS),[62-65] and the International Federation of Clinical Chemistry[12-17]; and books devoted to quality assurance practices in clinical laboratories.[23,127]

CONTROL OF PREANALYTICAL VARIABLES

The responsibility for accurate and timely test reports generally lies with the laboratory, but many problems can arise before and after the analysis of the submitted specimens. To monitor and control these errors, it is essential to perform a systems analysis of the laboratory and to identify the types of preanalytical variables.

Systems Analysis

The operation of the clinical laboratory can be viewed as a series of processes, each of which has potential sources of error. Table 19-1 shows the processes that take place from the time of the physician's initial request for a test to the time of the final interpretation of the test result. This "systems analysis" identifies the critical processes for a typical laboratory; however, each laboratory situation is somewhat different, and there may be additional processes and additional sources of error. It is important for each laboratory to perform a

TABLE 19-1 Laboratory Testing Processes and Their Potential Errors

Process	Potential Errors
Test ordering	Inappropriate test
	Handwriting not legible
	Wrong patient identification
	Special requirements not specified
	Cost or delayed order
Specimen acquisition	Incorrect tube or container
	Incorrect patient identification
	Inadequate volume
	Invalid specimen (e.g., hemolyzed or too dilute)
	Collected at wrong time
	Improper transport conditions
Analytical measurement	Instrument not calibrated correctly
	Specimen mix-up
	Incorrect volume of specimen
	Interfering substance present
	Instrument precision problem
Test reporting	Wrong patient identification
	Report not posted in chart
	Report not legible
	Report delayed
	Transcription error
Test interpretation	Interfering substances not recognized
	Specificity of test not understood
	Precision limitations not recognized
	Analytical sensitivity not appropriate
	Previous values not available for comparison

systems analysis of its own laboratory testing system to identify those areas where errors are likely to occur.

Once the processes have been documented, the processes that are most susceptible to error should be identified and should receive the most attention. Many times, the processes that lead to the greatest number of complaints, such as lost specimens or delayed results, are judged to be most important, even though other steps, such as the appropriateness of test selection and the acceptability of a specimen, may be of greater importance for optimal medical care. Guidelines describing procedures for specimen handling are available from organizations such as the NCCLS. Documents by accrediting agencies such as the CAP,[18] Centers for Disease Control and Prevention, and state regulatory agencies are also helpful in this regard.

Types of Preanalytical Variables

It is difficult to establish effective methods for monitoring and controlling preanalytical variables because many of the variables are outside the traditional laboratory areas (see Chapter 17). Monitoring preanalytical variables requires the coordinated effort of many individuals and hospital departments, each of which must recognize the importance of these efforts in maintaining a high quality of service. Accomplishing such monitoring may require support from outside the laboratory, particularly from the institution's clinical practice committee or some similar authority. Variables to consider include the following:

Test Usage and Practice Guidelines

Traditionally, laboratory test utilization has always been monitored or controlled to some degree, but current emphasis on the cost of medical care and government regulation of medical care has increased the importance of this factor. Clinical practice committees may decide that only certain tests are necessary for emergency care and may therefore limit the availability of kind and volume of requests. Peer review audits may lead to the development of other guidelines concerning the appropriate use of diagnostic tests in different clinical situations. Numerous patient care strategies and guidelines are being developed that directly impact laboratory usage.[44] For example, implementation guidelines for the use of bleeding times at the University of Massachusetts Medical Center resulted in a substantial reduction in test requests.[61] Careful monitoring of test requests and their appropriateness is likely to increase in importance, and the laboratory will likely have a role in identifying situations in which test utilization can be optimized and in providing in-service education to effect changes in ordering patterns.

Patient Identification

Correct identification of patients and specimens is a major concern for laboratories. The highest frequency of errors occurs with the use of handwritten labels and request forms. One method for checking identification is to compare identifiers such as the patient's name and his or her unique hospital number. The identification on the specimen label should also correspond with the identification on the requisition form. The use of plastic embossed patient identification cards to imprint the patient's name on test request forms and on blood collection labels can eliminate transcription and identification errors but does not guarantee that the patient name on the labels correctly identifies the donor of the specimen. The integration of bar code technology into the analytical systems that are used by clinical laboratories has significantly reduced identification problems (see Chapter 11).

Turnaround Time

Delayed and lost test requisitions, specimens, and reports have been major problems for laboratories. An essential feature for monitoring the cause of delays is the recording of

the actual times of specimen collection, receipt in the laboratory, and reporting of test results. This has been done manually by placing time stamps in key locations such as blood-drawing centers, specimen-processing stations, result-reporting areas, and wards or chart-posting areas. It also has been done more effectively by programming computer systems to automatically document the times of test requests, specimen acquisition, processing, analysis, and reporting.[77] Turnaround time has been monitored like any other QC variable, and limits established to flag "out-of-range" specimens. Lists of delayed specimens also provide a powerful mechanism for detecting lost specimens or reports. Resolution of problems in this area is aided by a systems analysis of the laboratory operations, which would help identify those steps and areas that cause delays and disruptions in service. A good system for monitoring patient, specimen, and information flow may be obtained by integration of the light wand and/or bar code or optical character identification system with a computer that could automatically track each specimen at each of the steps from test request to result posting.

Laboratory Logs

When the serum aliquot tubes arrive in the laboratory, various logging and monitoring systems are necessary. In laboratories without computerized reporting, a request and/or report form generally accompanies the specimens. One should check that the patient name and identification number and the tests requested on the form match the information on the label of the specimen tube. The specimen should be inspected to confirm adequacy of volume and freedom from problems that would interfere with the assay, such as lipemia or hemolysis. The specimens are then stored appropriately, and the identification information and arrival time are recorded in a master log. If the analyses are performed in batches, specimen identification generally is recorded in specific locations on the worksheets using the information on the tube labels. After analysis, the results are recorded on the worksheet, and if both the assay and the individual test results pass the QC criteria, the test results are transferred to the result forms for reporting. However, before reporting the results, a second technologist should verify the adequacy of the QC and should check for transcription errors by comparing the results on the report forms with those on the master log. Specimens that require further analysis because of dilution or assay problems should be indicated either on the master log or on a delayed report log.

Transcription Errors

In laboratories where electronic identification and tracking has not been implemented, a substantial risk of transcription error exists from manual entry of data even with the double checking of results. Computerization will reduce this type of transcription error as such systems have error detection routines programmed into the terminal entry functions, such as check digits, limit checks, test correlation checks, and verification checks with master hospital files (see Chapters 11 and 18).

Patient Preparation

Laboratory tests are affected by many factors, such as recent intake of food, alcohol, or drugs, and by smoking, exercise, stress, sleep, posture during specimen collection, and other variables (see Chapter 17). Proper patient preparation is essential for the test results to be meaningful. Although responsibility for this usually resides with personnel outside the laboratory, the laboratory must define the instructions and procedures for patient preparation and specimen acquisition. These procedures should be included in hospital procedure manuals and should be transmitted to patients in both oral and written instructions. Compliance with these instructions is monitored directly when the laboratory employs its own phlebotomists. Specific inquiry should be made regarding patient preparation before specimens are collected, and efforts should be made to correct noncompliance. For tests in which standardization of the collection is very important (such as for plasma catecholamines), specimens should be collected in a controlled environment, such as a clinical testing unit.

Specimen Collection

The techniques used to acquire a specimen affect many laboratory tests (see Chapter 2).[88] For example, prolonged tourniquet application causes local anoxia to cells and excessive venous back pressure. The anoxia causes small solutes (such as potassium) to leak from cells, and the venous pressure concentrates cells, proteins, and substances bound to proteins (such as calcium). Blood collected from an arm into which an intravenous infusion is running can be diluted or contaminated. Hemolysis during and after collection alters the concentration of any analyte that has a red blood cell/plasma concentration differential. Improper containers and incorrect preservatives greatly affect test results and make them inappropriate. One way to monitor and control this aspect of laboratory processing is to have a specially trained laboratory team assigned to specimen collection. All members of the team should be given explicit instruction in the proper methods of specimen collection. The identification of the person collecting a specimen should be maintained. Individuals who process the specimens should be trained to look for and document collection problems. Physicians should be encouraged to report clinically inconsistent results. Similarly, errors detected by limit checks, delta checks (differences between consecutive results on individual patients), or other algorithms should be recorded. Any collection problems should be reviewed with the individuals collecting the specimens. Pride of workmanship should be encouraged, and quality performance should be rewarded.

Specimen Transport

The stability of specimens during transport from the patient to the laboratory is seldom monitored; however, this aspect

may be critical for some tests when performed locally and for most tests when sent to regional centers and commercial laboratories.[63] Most laboratories have recommendations for specimen storage and transport, but many of these are empirical and lack adequate scientific documentation. Even the definition of "stability" is not well agreed upon; some investigators accept changes less than 10%,[50,128] and others relate stability to medically significant changes[80] or a percentage of the established analytical variability.[96]

In controlling specimen transport, the essential feature is the authority to reject specimens that arrive in the laboratory in an obviously unsatisfactory condition (such as a thawed specimen that should have remained frozen). As with other QC procedures, a small number of problems are expected, but if the error rate gets too large, there is a necessity for systems analysis of transport procedures, with resulting modifications. In tests in which stability is a major problem, the design of specific control procedures appropriate for those tests may be necessary.

Specimen Separation and Aliquoting

Separating and aliquoting blood specimens are more directly under the control of the laboratory. The main variables are the centrifuges, the containers used, and the personnel.

Centrifuge Performance

Centrifuges are discussed in Chapter 1. For QC purposes, centrifuges should be monitored by checking the speed, timer, and temperature.

Container Monitoring

Collection tubes, pipettes, stoppers, and aliquot tubes are sources of calcium and trace metal contamination. Also, glass beads or other materials added to blood specimens to aid in the separation of serum from cells may cause contamination. Each lot number of materials used should be tested for contamination by calcium and possibly other elements. Cork stoppers should not be used on specimens intended for calcium determinations because false elevations of 10% to 50% may occur. Some of the plasticizers used in making plastic containers interfere with drug analyses. Also, some plastic materials adsorb trace amounts of some analytes and should not be used for substances in low concentration, such as parathyroid hormone.[41] Because of the intricate relationships between specimen processing and analytical testing, supplies and processing procedures should not be changed without consulting the personnel responsible for the analytical testing (see also Chapter 2).

Personnel Monitoring

As in other areas of the laboratory, the personnel who process the laboratory specimens should be carefully trained and supervised. A written procedure manual should be available in the area. "Fast-track" mechanisms should be established for the processing of emergency specimens. QC mechanisms should monitor both personnel performance and personnel safety. An important part of performance is throughput time, which can be calculated if one records the specimen arrival time and the time when processing is completed. Weekly or monthly summary statistics are an effective method for monitoring processing time. Also, the identification of the technologists should be recorded to facilitate the detection and correction of problems.

In optimizing the efficiency of a specimen-processing laboratory, there is a trade off between the time it takes to record and check parameters and the error rates or inconsistencies of the function. However, these records are necessary for documenting the daily operation and for helping to identify systematic problems.

An elegant system for monitoring manual clerical functions has been developed to detect errors in blood banking records.[92] In this system, known errors are discretely introduced into the system using fictitious patients. The types of errors introduced are chosen to represent errors likely to occur or errors that cause major problems. The fictitious reports are routed to dummy locations and eventually returned to the QC technologist. One can calculate the efficiency of the laboratory error detection program by comparing the number of fictitious errors discovered with the number introduced. This efficiency factor is then used to estimate the actual laboratory error rate based on the number of true errors discovered in the laboratory. The implementation of this scheme requires the cooperation of laboratory personnel and the involvement of a QC specialist. By a combination of paranoia and pride of workmanship, most personnel are more conscientious when they know they are being monitored. Substantial increase in the rate of error detection was observed shortly after this plan was implemented in the blood bank. Public display of individual error rates encourages pride of workmanship.

CONTROL OF ANALYTICAL VARIABLES

Many analytical variables must be controlled carefully to assure accurate measurements by analytical methods. Reliable analytical methods are obtained by a careful process of selection, evaluation, implementation, maintenance, and control (see Chapter 14). Efficient, effective, and uninterrupted laboratory service requires many procedures aimed at preventing the occurrence of problems. Laboratories may experience different problems with the same analytical methods owing to different amounts of effort being allocated to the care and support of those methods.

Certain variables—water quality, calibration of analytical balances, calibration of volumetric glassware and pipettes, stability of electrical power, and the temperature of heating baths, refrigerators, freezers, and centrifuges—should be monitored on a laboratorywide basis because they will affect many of the methods in the laboratory (see Chapter 1). In addition, there will be certain variables that relate more directly to individual analytical methods, and these require

that procedures be developed to deal specifically with the characteristics of those methods.

Choice of Analytical Methodology

The selection and evaluation of analytical methods are discussed in Chapters 14 and 15. It is important to recognize, however, that the initial evaluation of a method often takes place in a setting somewhat more idealized than the production setting. It is therefore desirable to have a start-up period in the service laboratory before test results are to be reported. This period allows time to (1) discover any additional problems, (2) develop maintenance programs that alleviate those problems, and (3) train a sufficient number of analysts to support the routine service operation.

Reference Materials and Calibration

The quality of the calibrators and the calibration procedure used are major factors in determining the reliability of the analytical values obtained with a procedure. To appreciate the problems in standardization and calibration, knowledge of the overall structure of an accuracy-based measurement system is necessary. Uriano and Cali[98] and Tietz[97] have defined a hierarchy of analytical methods and reference materials that shows the relationship between reference materials and analytical methods of different quality. Figure 19-7 illustrates how "field methods" are related to "reference methods" by "secondary reference materials" and how reference methods are related to "definitive methods" by "primary reference materials."

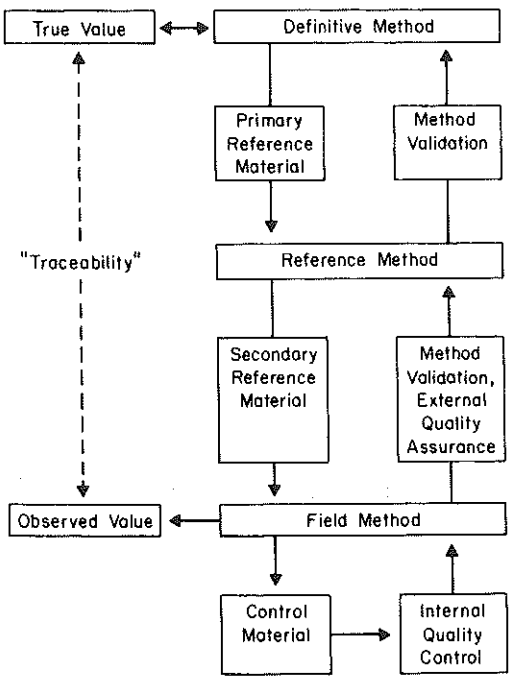

Figure 19-7 Structure of an accuracy-based measurement system showing relationships among reference methods and materials.

The practical meaning of this measurement structure has been discussed by Tietz.[97] The highest quality methods, the *definitive methods*, are to be used to validate reference methods and primary reference materials. The highest quality reference materials, namely *primary reference materials*, should be used in the development and validation of reference methods, the calibration of definitive and reference methods, and the production of secondary reference materials. *Reference methods* should be used to validate field methods. *Secondary reference materials* should be used to provide working calibrators for field methods and to assign values to control materials. *Control materials* are used only to monitor field methods.

Definitions

The following definitions for these materials have been developed by the National Reference System for the Clinical Laboratory (NRSCL)[62]:

Reference material (RM): "A material or substance, one or more whose property values are sufficiently homogeneous and well established to be used for the calibration of an apparatus, the assessment of a measurement method, or for assigning values to materials."

Certified reference material (CRM): "A reference material, accompanied by a certificate, one or more whose property values are certified by a procedure that established its traceability to an accurate realization of the unit in which the property values are expressed, and for which each certified value is accompanied by an uncertainty at a stated level of confidence." For example, standard reference materials from the U.S. National Institute of Standards and Technology (http://www.nist.gov) are considered CRMs.

Calibration material and/or calibrator: "A material (e.g., solution) or a device of known, or assigned quantitative and/or qualitative characteristics (e.g., concentration, activity, intensity, reactivity) used to calibrate, graduate, or adjust a measurement procedure or to compare the response obtained with the response of a test specimen and/or sample."

Control material: "A device, solution, lyophilized preparation, or pool of collected human or animal specimen, or artificially derived material, intended for use in the quality control process."

Use

To illustrate the use of these materials, a field (routine) method would be traceable to a reference method when it has been evaluated against that method or when it has been calibrated with a secondary reference material or calibrator whose value was established by analysis with a reference method. The reference method itself should have been validated against a definitive method and calibrated with a primary reference material or CRM whose value was established by the definitive method. Proper choice of calibrating materials establishes the traceability of the analytical results

to the "true value" through the structure of the measurement system (Figure 19-7).[30] Note also that the use of control materials solely for internal quality control does not establish traceability, but use of such materials in external quality assurance may validate field methods against reference methods and thereby may establish traceability. (See Chapter 14 for a discussion of traceability.)

The selection of reference materials is therefore critical in validating the performance of an analytical method (see Chapter 1). CRMs should be used at least in the initial evaluation studies and in establishing the acceptability of calibrators used in routine service. The specific characteristics of calibrators should be documented, along with the number of different concentrations of calibrating solutions and the frequency of their use. These latter choices depend on the characteristics of the analytical method, particularly the stability, reproducibility, and linearity.

Documentation of Analytical Protocols

Step-by-step procedures for performing analytical determinations are critical if the methods are to provide the same results when used by different analysts over a long period of time. Maintaining such consistency requires written protocols or method and procedure manuals. The essential information to be contained in such documents is outlined in Box 19-1. More detailed guidelines are provided in an NCCLS document.[64] Method manuals should be reviewed annually and revised whenever changes occur. Although once a problem because of the time required to retype procedures, the availability of word processors has alleviated this difficulty and permitted rapid revisions whenever changes occur. It is also a good practice to retain outdated procedures in an archival file.

Establishment of Reference Intervals

The details for the establishment of reference values are presented in Chapter 16. An NCCLS document is also available on the topic.[66]

Monitoring Technical Competence

The personal characteristics and techniques of individual analysts may greatly affect certain analytical methods, particularly manual methods. Proper training of laboratory personnel to achieve uniformity in technique is important, as is scheduling sufficient routine service to maintain proper techniques. In training personnel on new analytical methods, it is helpful to have written lists of objectives that outline the critical tasks and knowledge that must be mastered. Having such objectives ensures systematic instruction that covers the critical points. Before performing analyses for clinical use, the technical competence of the personnel should be checked, and practice runs should be performed. Periodic monitoring of competency may be difficult, but incident reports and results from internal and external QC checks will identify specific problems; these problems should be discussed directly with the personnel involved. In-service and continuing education programs will help maintain and improve competence. Employee conferences will also help uncover nontechnical problems that may affect work quality.

BOX 19-1 Outline for a Procedure Manual

A. *Procedure name:* List principal name of procedure first, alternative names next. List commonly used abbreviations.
B. *Clinical significance:* Give a brief explanation of how the test is used in clinical medicine. Include reference intervals for specific diseases and recommended diagnostic and therapeutic action limits.
C. *Principle of method:* Give a brief statement of the principles on which the method is based.
D. *Specimen:* List type of specimens that can be used and recommended volume and minimum volume. Indicate conditions that render the specimen unacceptable, such as hemolysis or lipemia. List patient preparation procedures. Provide instruction for specimen handling before testing.
E. *Reagents and equipment:* Provide a list of reagents in order of their use, including standards. Indicate the names and addresses of suppliers and detailed instructions for preparation, including checks to be performed before use. List equipment used and special precautions required.
F. *Procedure:* This should be a step-by-step description, including calibration and QC procedures. There should be enough detail so that the assay could be performed by a person unfamiliar with the test. The necessary calculations should be included.
G. *Reference values:* List the reference intervals for healthy subjects. Indicate parameters such as age, sex, or race that affect reference values. Include the nature of the population studied, the number of subjects, and the date or reference for the original work.
H. *Comments:* Include any special analytical variables affecting the test, such as pH or temperature. Include effects of commonly used drugs, any dangers or personal hazards in the procedure, and any special safety precautions and procedures.
I. *References:* Give the primary literature references that describe the method or the references upon which the method is based.

Inventory Control of Materials

Stable operation of laboratory methods is critically dependent on the materials used with the methods. Procedures are necessary to inventory materials and initiate orders when supplies are low. These procedures must be tailored to the particular reagents and supplies that are in use. In general, when materials are stable and changes in lot numbers cause problems, large stocks should be maintained, though this may be limited by economic considerations, shelf life, and storage space. Adequate inventory should be maintained to allow time for additional shipment and testing of additional supplies should the current shipment be unsatisfactory. Formal inventory control procedures will help minimize required storage by initiating orders when stock reaches a certain predetermined level. Many companies will ship

reagents on a standing order once usage rates are established. In fact, with the arrival of rapid transportation and delivery capabilities, a laboratory is now able to order reagents and supplies and receive them in a very short period of time—a "just-in-time" approach to inventory control.

Input Control of Materials

Along with inventory management, the quality of materials should be monitored when they are received. Interruptions in service can be prevented by testing the adequacy of materials before their introduction for routine use. It is particularly important that patient results from new lots of reagents and calibrators be compared with those obtained with previous lots. New lots of blood-drawing tubes, processing tubes, and the like should receive some parallel or comparison testing before their routine use. In establishing pretesting procedures for monitoring incoming materials, it should be recognized that this kind of testing is costly, both in time and money.

Another part of input control is the proper labeling of reagents and materials. Proper identification should include the name, lot number (particular manufacturing batch), concentration, date received, date prepared, date opened, date of expiration, and recommended storage conditions. In practice, such information is provided by manufacturers via a human-readable bar code.

Monitoring Method Changes

An essential tool for solving analytical problems is a record or log of all changes and problems occurring with a method. These should include the date, time, analyst, and any changes in lots of reagents, materials, or calibrators. All instrument maintenance should be recorded, including all work performed by service personnel from outside the laboratory. The occurrence of control problems should be indicated, along with actions taken to resolve the problems. Periodic review of these logs should lead to implementation of preventive maintenance programs, based on the frequency of occurrence of particular problems.

CONTROL OF ANALYTICAL QUALITY USING STABLE CONTROL MATERIALS AND CONTROL CHARTS

In the routine operation of clinical laboratories worldwide, the performance of analytical methods is routinely monitored by analyzing specimens whose concentrations are known followed by comparing the observed values with the known values. The known values are usually represented by an interval of acceptable values, or upper and lower limits for control (control limits). When the observed values fall within the control limits, the analyst is assured that the analytical method is functioning properly. When the observed values fall outside the control limits, the analyst should be alerted to the possibility of problems in the analytical determination. A number of books are available that discuss the application of QC in the operation of the clinical laboratory.[9,23,107,109,110]

Control Materials

Specimens that are analyzed for QC purposes are called control materials. They are required to be stable, available in aliquots or vials, and amenable to being analyzed periodically over a long time. There should be little vial-to-vial variation so that differences between repeated measurements are attributed to the analytical method alone. The control material should preferably have the same matrix as the test specimens of interest (e.g., a protein matrix may be best when serum is the test material to be analyzed by the analytical method).[59] Materials from human sources have generally been preferred, but because there is some risk of hepatitis infection, bovine materials offer a certain advantage in safety and are more readily available. The concentration of analyte should be in the normal and abnormal ranges, corresponding to concentrations that are critical in the medical interpretation of the test results.

In practice, clinical laboratories are able to purchase materials from one of several companies that manufacture control sera or "control products." These are generally supplied as liquid or lyophilized materials that are reconstituted by adding water or a specific diluent solution. Also available are materials having matrices representing urine, spinal fluid, and whole blood. Liquid control materials are also available and have the potential advantage of eliminating errors caused by reconstitution. However, the matrices of these liquid materials contain other materials that may be a potential source of error with some analytical methods and instruments.

When selecting commercial control materials, there are several other considerations in addition to the matrix of the product. Stability is critical because it is often desirable to purchase a year's supply of one manufacturing lot or batch. Different batches (or lot numbers) of the same material will have different concentrations, which require new estimates of the mean and standard deviation. The size of the aliquots or vials should be convenient for the analytical methods to be monitored. Larger-sized vials are generally less expensive (on a per milliliter basis), but unused materials may eliminate any savings. Two or three different materials should be selected to provide concentrations that monitor performance at different medical decision levels. There may be some advantage in selecting materials from different manufacturers to minimize possible problems with a given manufacturing process. Alternatively, a series of materials designed by one manufacturer to have a certain relationship between concentrations can be used to gain additional information regarding linearity and accuracy.

Control products are purchased as assayed or unassayed materials. Assayed materials come with a list of values for the concentrations that are expected for that material. This list often includes both the mean and standard deviation for several of the common analytical methods and preferably for

a reference method used to measure a particular analyte. Because of the work required to determine these values, the assayed materials are in general more expensive. Although the stated assay values are useful in selecting the desired materials, it is advisable to determine the mean and standard deviation in the user's laboratory because this process improves the performance characteristics of statistical control procedures.

General Principles of Control Charts

The most common method of comparing the values observed for control materials with their known values is through the use of control charts. Control charts are simple graphical displays in which the observed values are plotted versus the time when the observations were made.* The known values are represented by an acceptable range of values, as indicated on the chart by lines for upper and lower control limits. When the plotted points fall within the control limits, this is generally interpreted to mean that the method is performing properly. When points fall outside the control limits, problems may be developing.

The control limits are usually calculated from the mean ($\bar{x}$) and standard deviation (s) obtained from repeated measurements on the known specimens by the particular analytical method that is to be controlled. The mean ($\bar{x}$) and standard deviation (s) are calculated from the following equations:

$$\bar{x} = \frac{\sum x_i}{n}$$

$$s = \sqrt{\frac{n\sum_{i=1}^{n} x_i^2 - \sum_{i=1}^{n}(x_i)^2}{n(n-1)}}$$

where x_i is an individual control observation and n is the number of observations in the time period being monitored (see Chapter 14). The initial estimate should be based on measurements obtained over a period of at least 1 month when the method is working properly. These conditions are necessary because the measurements are used to characterize the distribution of values that is expected during stable routine operation of the analytical method.

The initial estimate may not be entirely reliable owing to the low number of data points and possible outliers in the data. The estimates are revised when more data have been accumulated by recording n and the summations of x_i and x_i^2, then using the cumulative totals in the equations above to give cumulative means and standard deviations. The effects of outliers can be minimized by eliminating values exceeding the mean by more than ±3.1 to 3.8s (where the exact factor depends on the total number of data points: 3.14 for $n = 30$; 3.22, $n = 40$; 3.33, $n = 60$; 3.41, $n = 80$; 3.47, $n = 100$; 3.66, $n = 200$; 3.83, $n = 400$).

It is assumed that error distribution of the analytical method is Gaussian (see Chapter 14). The control limits are set to include most of the control values, usually 95% to 99.7%, which correspond to the mean ±2 or 3 standard deviations. Because it should be a relatively rare occurrence to observe a value in the tails of the distribution (only 1 out of 20 times for 2s limits and 3 out of 1000 for 3s limits), such an observation is suspect and suggests that something has happened to the analytical method. Such an occurrence could have caused a shift in the mean (an accuracy problem), which would result in a higher probability for exceeding the limits, or it could have caused an increase in the standard deviation (a precision problem), which would widen the distribution and also result in a higher probability for exceeding the limits.

Figure 19-8, *A* illustrates how the distributions of control values will appear for three different situations: (a) stable performance where only an occasional observation exceeds the control limits; (b) occurrence of a systematic error that shifts the mean of the distribution and causes a much higher expectation or probability of observing control values outside one of the control limits; and (c) occurrence of an increase in random error or imprecision, which widens the distribution and causes a much higher probability of observing a control value outside either of the control limits.

Control charts are used to compare the observed control values with the control limits and to provide a visual display that can be quickly inspected and reviewed. These charts have the concentration or observed value plotted on the y-axis versus time of observation on the x-axis. It is common practice to plot 1 month's data on a chart, usually only one or two points a day, but the time axis should be chosen to be appropriate for the method being monitored. An example of a control chart is shown in Figure 19-8, *B*, where the control values represent the three situations in Figure 19-8, *A*, with 10 values per situation for a total of 30 values. When the analytical method is operating properly, the control values fall predominantly within the control limits. When there is an accuracy problem, the control values are shifted to one side, and there may be several values in a row falling outside one of the limits. When there is a precision problem, the control values fluctuate much more widely, and there may be values exceeding both the upper and lower control limits.

Interpretation of the control data is guided by certain decision criteria or control rules, which define when an analytical run is judged "in control" (acceptable) or "out of control" (unacceptable). These control rules are given symbols, such as A_L, or n_L, where A is the abbreviation for a statistic n is the number of control observations, and L refers to the control limits. For example, 1_{3s} refers to a control rule where 1 observation exceeding the mean ±3s control limits is the criterion for rejecting the analytical run.

*Although the discussions in this chapter imply that plots are manually prepared, in actual practice, a wide variety of computer software packages are available for statistically calculating and plotting QA data.

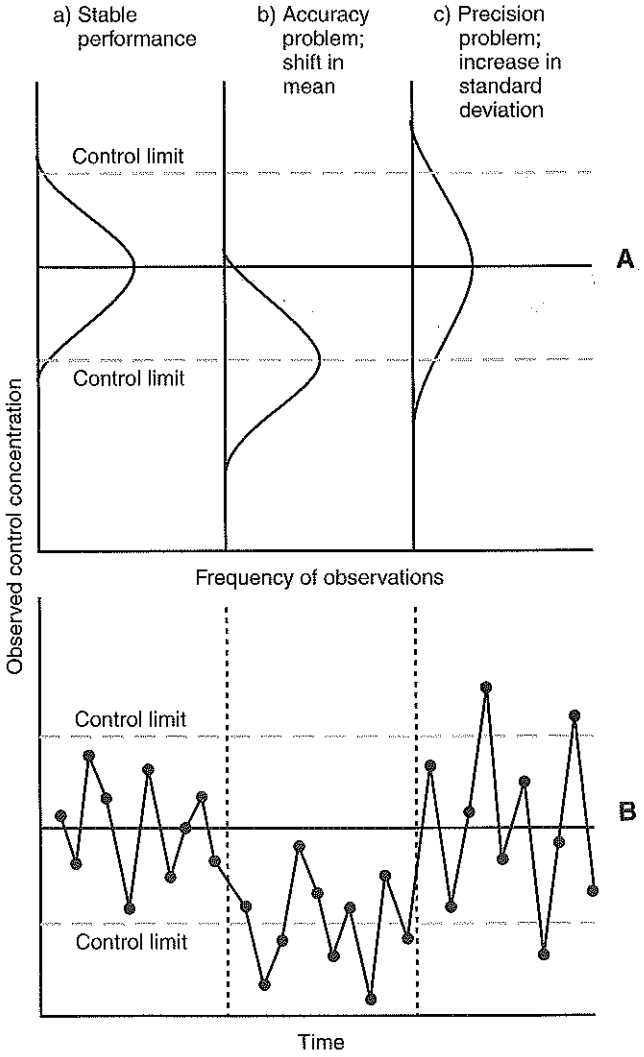

Figure 19-8 Conceptual basis of control charts. **A,** Frequency distributions of control observations for different error conditions. **B,** Display of control values representing those distributions when concentration is plotted versus time on a control chart.

"Analytical run" is used here to refer to that segment of data for which a decision on acceptability is to be made. This is the group of patient results that is to be reported, based on the control results available for inspection at that time.

The total number of control observations available for inspection when a decision is to be made on the acceptability of an analytical run is designated as "*N*." For example, when there is one control observation preceding and one following a group of 10 patient samples whose results are to be reported, there are two control observations in that analytical run.

The different control procedures discussed here have different performance capabilities, depending on the control rules and the number of control observations chosen. These choices should be related to the quality goals set by the laboratory. Many of the procedures in use today have not been chosen for best performance, but rather for ease of use in manual implementation or rule availability in the QC software of instruments and laboratory information systems. Tetrault and Steindel contend that the best set of control rules will vary from method to method.[93] Knowledge of the performance characteristics of control procedures is necessary to select control rules and n's that will detect relevant laboratory problems without causing too many "false alarms" (rejections when there are no analytical problems). Experienced analysts often employ a series of informal rules or judgments to reduce the number of false alarms without knowing their effects on the detection of real problems, or true alarms. There should be some quantitative assessment of these two characteristics, false alarms and true alarms, whenever capabilities of new control procedures are assessed or established control procedures are reviewed.

Performance Characteristics of a Control Procedure

The performance of a control procedure is described by its probability for rejection.[121] Probability refers to the likelihood that an event will occur; in this case, the event is the rejection of an analytical run. Ideally, there should be no rejections of analytical runs when the analytical method is performing properly. Alternatively, when analytical errors occur, the control procedure should provide a rejection signal. This corresponds to having a probability of 0.00 in the first situation and a probability of 1.00 in the second.

The term "probability for false rejection" (p_{fr}) is used to describe the first situation, where there are no analytical errors present except for the inherent imprecision or inherent random error of the analytical method. (There is always some random error associated with an analytical method, even when it is working properly. This is the random error that is estimated by the replication experiment during method evaluation studies.) When only this inherent random error is present, without any additional errors, the probability for false rejection should be zero. The frequency of false rejections is critical, because false rejections are like false alarms. Too many false alarms cause the analyst to disregard the alarm system, even when the alarm is occurring as a result of real errors that should be corrected.

"Probability for error detection" (p_{ed}) is the term used to describe the second case, where there is an analytical error in addition to the inherent or background random error. The probability for error detection should be high (near 1.00) when these errors are large enough to invalidate the quality goals for the analytical method. Unfortunately, this is difficult to achieve because the control procedure is attempting to detect a signal (additional error) in the presence of noise (inherent random error).

These critical performance characteristics—probability for false rejection and probability for error detection—are summarized by graphs of probability for rejection (*y*-axis) versus the size of analytical error (*x*-axis). Graphs such as

that shown in Figure 19-9 are called power functions because they describe the statistical power of the control procedure.[119] The different lines on the graph represent different numbers of control observations (e.g., $n = 1, 2$, and 4 for the three lines on this graph). The probability for false rejection is given by the y-intercept, the point where each line intersects the y-axis. For this control procedure with n from 1 to 4, p_{fr} is 0.01 to 0.02, or 1% to 2%. The probability for error detection can be determined for any size error by first locating the size of the error on the x-axis, drawing a line up to intersect the power function curve, drawing a horizontal line from the point of intersection to the y-axis, and reading the probability for rejection from the scale on the y-axis. For this control procedure, p_{ed} is 0.13 for $n = 1$, 0.22 for $n = 2$, and 0.48 for $n = 4$. Thus there is a 13% to 48% chance of detecting an error of this size with this control procedure, depending on the number of control observations used.

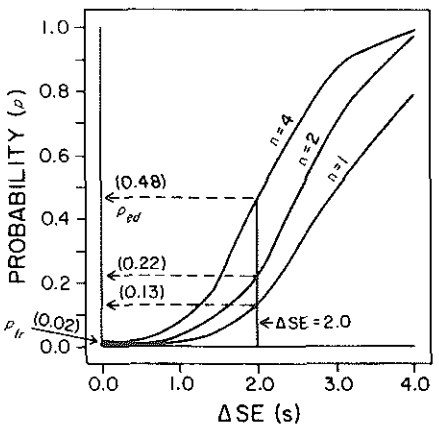

Figure 19-9 Power function graph presenting probability for rejection on the y-axis versus size of error on the x-axis. The different lines represent numbers of control observations, in this case $n = 1$, 2, and 4.

Two power function graphs are necessary, one to describe the performance for random error (RE) and the other for the performance for systematic error. For RE, as shown in Figure 19-10, *A*, the x-axis is labeled ΔRE. A value of 1.0 corresponds with the original standard deviation of the analytical method, a value of 2.0 to a doubling of that standard deviation, 3.0 to a tripling, and so on. For systematic error (SE), the x-axis is labeled ΔSE (see Figure 19-10, *B*). A value of $1.0s$ corresponds to a systematic shift equivalent to the size of the standard deviation, a value of $2.0s$ to a shift equivalent to two times s, and so on.

Power functions are determined by mathematical calculations or by computer simulation studies, the latter having been used in clinical laboratories to characterize many of the commonly used control procedures.[35,119] Power functions are useful for evaluating the performance capabilities of individual control procedures, for comparing the performance of different control procedures, and for designing new procedures with improved performance characteristics. The best control procedure is the one with the lowest probability for false rejection and the highest probability for detecting those errors that are large enough to invalidate the analytical quality goals for the method.

The sizes of the analytical errors that must be detected if the control procedure is to maintain a specified quality can be determined from a general analytical model for translating quality requirements into laboratory process specifications.[126]

$$TE_a = bias_{meas} + \Delta SE_{cont} s_{meas} + z\Delta RE_{cont} s_{meas}$$

TE_a is the analytical quality requirement expressed as an allowable total error. Minimum total error requirements are

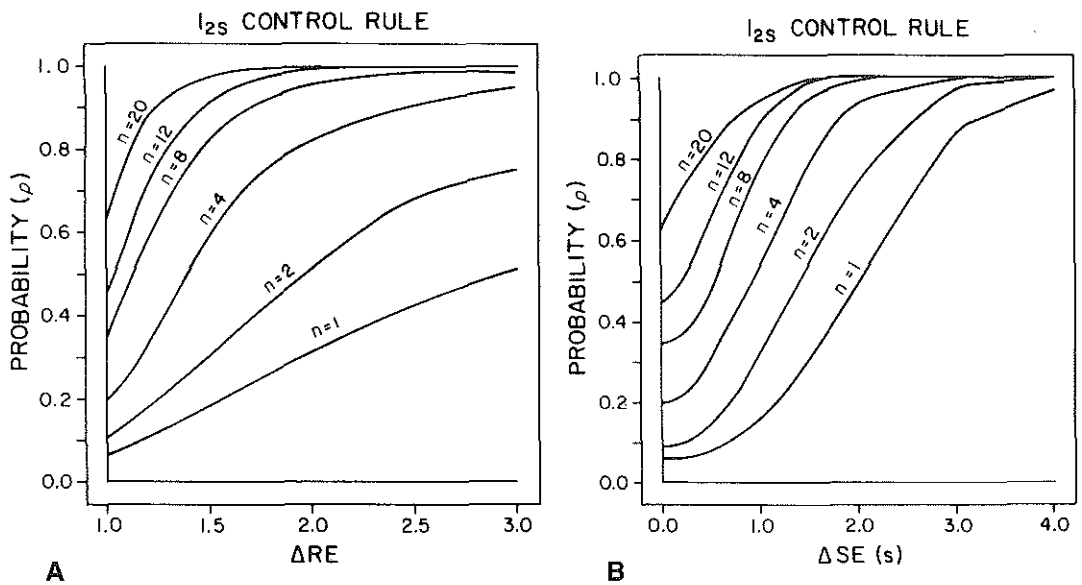

Figure 19-10 Power functions for 1_{2s} control rule. **A,** Random error. **B,** Systematic error. *(From Westgard JO, Groth T. Power functions for statistical control rules. Clin Chem 1979;25:863-9.)*

defined by the CLIA proficiency testing criteria for acceptable performance (see later section). $Bias_{meas}$ is the analytical measurement bias (stable inaccuracy), s_{meas} is the analytical measurement standard deviation (stable imprecision), ΔSE_{cont} is the change in systematic error (unstable inaccuracy) to be detected by the control procedure, ΔRE_{cont} is the change in random error (unstable imprecision) to be detected by the control procedure, and z is related to the chance of exceeding the quality requirement. When z is 1.65, a maximum defect rate of 5% may occur before rejecting an analytical run.

This analytical model is solved for ΔSE_{cont} (by setting ΔRE_{cont} to 1.0) or for ΔRE_{cont} (by setting ΔSE_{cont} to 0.0) to determine the critical sizes of errors that must be detected to maintain performance within the specified quality

$$\Delta SE_{crit} = [(TE_a - |bias_{meas}|)/s_{meas}] - 1.65$$
$$\Delta RE_{crit} = (TE_a - |bias_{meas}|)/1.65 s_{meas}$$

ΔSE_{crit} is the critical systematic error that would shift the distribution enough to cause 5% of the test results to exceed TE_a; ΔRE_{crit} is the critical increase in random error that would widen the distribution enough to cause 5% of the test results to exceed TE_a ($z = 1.65$ for 5% on one side; $z = 1.96$ for 2.5% on each side).

For example, if TE_a were specified as 10 mg/dL at a concentration of 120 mg/dL, and s_{meas} were estimated as 2.0 mg/dL and $bias_{meas}$ as 0.0 mg/dL, ΔSE_{crit} would be 3.4s, and ΔRE_{crit} is 3.0. This indicates that the control procedure has to be able to detect a systematic shift equivalent to 6.8 mg/dL (3.4 × 2) and a random error equivalent to a standard deviation of 6.0 mg/dL (3.0 × 2).

With knowledge of these values for critical errors and the power functions for a control procedure, it is possible to make a critical assessment of the performance achievable by different statistical control procedures. The quality of the control procedures themselves can be evaluated and related to the quality goals defined for the laboratory.

The relationship between the quality requirement for a test, the imprecision and inaccuracy that are allowable, and the QC that is necessary are shown graphically by a chart of operating specifications (OPSpecs chart).[105] Figure 19-11 shows such a chart that has been prepared for a TE_a of 10%, single and multirules with n's that are commonly used in laboratories, and a p_{ed} of 0.90 or 90% error detection for systematic errors. This OPSpecs chart is derived from the analytical quality planning model shown earlier, setting ΔRE to 1.0, then rearranging as follows:

$$bias_{meas} = TE_a - (\Delta SE_{cont} + 1.65)s_{meas}$$

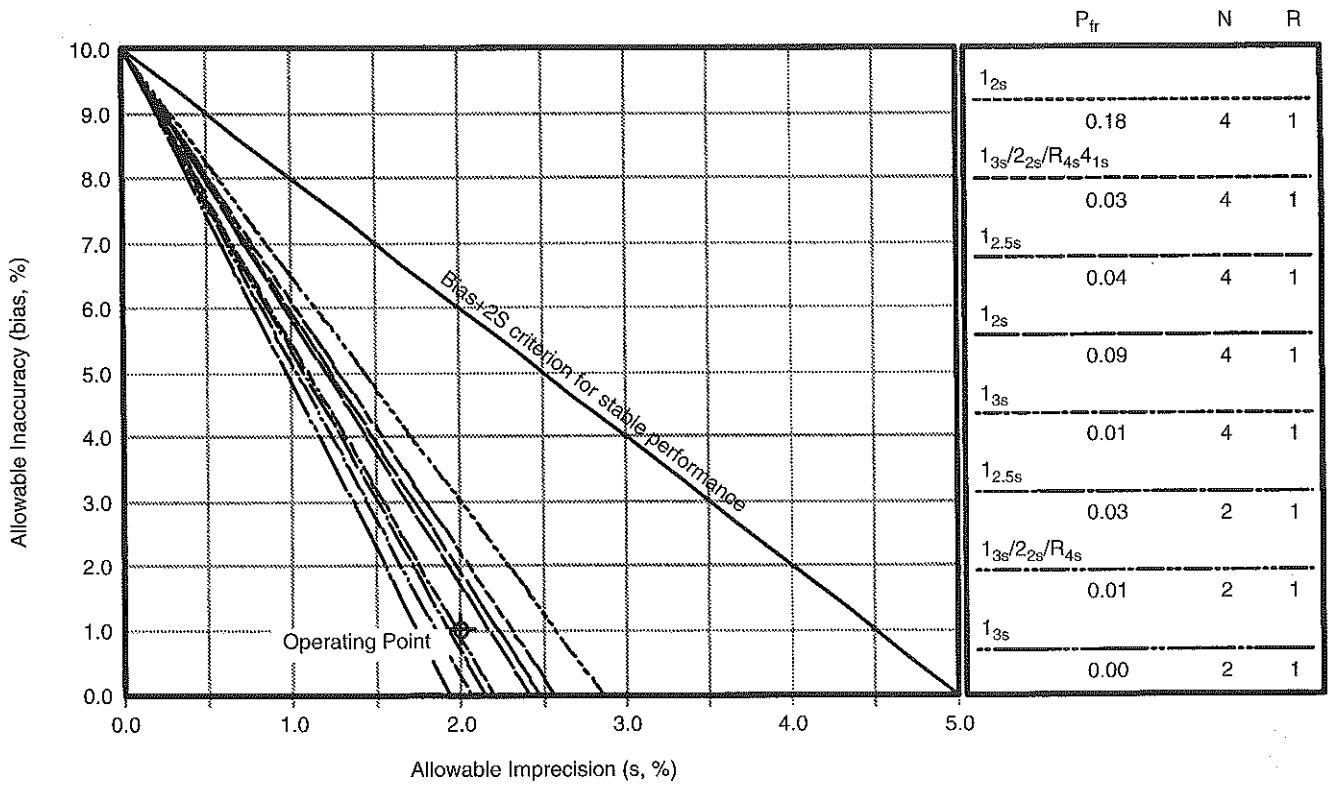

Figure 19-11 Operating specifications chart for an analytical quality requirement of 10% (TE_a) and 90% analytical quality assurance for systematic error. Allowable inaccuracy is plotted on the *y*-axis versus allowable imprecision on the *x*-axis.

Notice that this equation has the form of a straight line ($Y = a + bX$), where the y-intercept (a) is TE_a and the slope (b) depends on the sensitivity of the QC procedure. The value for ΔSE_{cont} is obtained from power curves for the control rules and n's of interest and for specified probabilities, such as 90% and 50%.[102] A plot of $bias_{meas}$ versus s_{meas} will describe the allowable limits of imprecision and inaccuracy for different control rules and different numbers of control measurements. A QC procedure can be selected by plotting the observed inaccuracy and imprecision as the method's operating point, then identifying the control rules and n's of the lines above the operating point.

For this example where the observed imprecision is 2.0% and the observed inaccuracy is 1.0%, the four lines above the operating point correspond to the top four QC procedures listed in the key on the right. All four will provide at least 90% detection of critical systematic errors, but their false rejection rates will vary from 0.03 to 0.18, or 3% to 18%. Appropriate choices would be the $1_{2.5s}$ single rule with $n = 4$ or the $1_{3s}/2_{2s}/R_{4s}/4_{1s}$ multirule with $n = 4$ to keep false rejections low.

Step-by-Step Process for Selecting QC Procedures

Laboratories should establish a systematic process for selecting appropriate QC procedures. The necessity for this is illustrated by the statement in the U.S. CLIA regulations[99,100] that "the laboratory must evaluate instrument and reagent stability and operator variance in determining the number, type, and frequency of testing calibration or control materials and establish criteria for acceptability used to monitor test performance during a run of patient specimens." Given that most laboratories must also satisfy certain national proficiency testing requirements, analytical requirements for quality have also been defined by regulatory or professional groups for many of the common tests.

1. Define the analytical quality requirement in the form of an allowable total error (TE_a).

   Use proficiency testing criteria as a practical starting point for defining the minimum quality that must be achieved.
2. Evaluate method performance to obtain estimates of imprecision and inaccuracy.

   Obtain initial estimates from replication and comparison of methods experiments. Obtain ongoing estimates from routine QC and proficiency testing surveys.
3. Obtain power function graphs for the control rules and n's of interest, or OPSpecs charts for the defined TE_a. Power function graphs and OPSpecs charts for commonly used QC procedures with n's of 2, 3, 4, and 6 are available in the scientific literature,[118,119] in workbook format,[106] and also from computer programs (EZ Rules and QC Validator 2.0, Westgard QC, Inc., Madison, Wis.—http://www.westgard.com).
4. Calculate the critical systematic error and draw a vertical line showing its location on the power function graph, or plot the observed imprecision and inaccuracy of your method on the OPSpecs chart for the TE_a of interest.
5. Assess the probabilities for error detection and false rejection.
6. Select control rules and n's that provide 90% detection of the critical systematic error and less than 5% false rejections. For very stable methods, consider 50% error detection if necessary to keep the number of control measurements and false rejections low.
7. Select a total QC strategy to provide an appropriate balance between statistical and nonstatistical QC procedures. With 90% error detection, depend on the statistical QC component and perform the minimal preventive maintenance, instrument function checks, and method validation tests required by good laboratory practice, manufacturers' instructions, and regulatory and accreditation guidelines.

   With 50% to 90% error detection, balance the efforts between statistical and nonstatistical QC procedures; improve method performance by reducing the bias and reducing imprecision.

   With less than 50% error detection, increase the efforts for nonstatistical QC to prevent problems from occurring, improve method performance, or consider replacing the method to achieve better imprecision and inaccuracy and more cost-effective operation of the testing process.
8. Reassess for changes in method performance as necessary. Cost-effective QC depends on doing the right QC to ensure the desired quality is achieved at minimum cost.[110] If method performance improves, less QC will be necessary; if method performance deteriorates, more QC will be necessary. Adjust the QC design as necessary for any changes in method performance.

Detailed applications based on calculated critical systematic errors have been presented for a multitest chemistry analyzer[48,124]; detailed applications using OPSpecs charts have been presented for automated immunoassays[60]; illustrative examples using OPSpecs charts have also been provided for a variety of tests in chemistry, hematology, coagulation, endocrinology, toxicology, and immunology.[106]

Manual application of this QC planning process is performed in just a minute using a workbook of OPSpecs charts that cover the range of analytical quality requirements from 1% to 50% and common single and multirules with n's from 2 to 6.[106] Computer support is necessary to use clinical quality requirements stated in the form of a medically important change or a decision interval for test interpretation; clinical requirements are more complicated and require an expanded quality planning model that accounts for additional preanalytical factors, such as within-run biological variation.[122]

With either manual or computer-supported QC planning, laboratories are able to identify appropriate control rules and the minimum number of control measurements that will ensure the desired quality is achieved at the minimum cost. These control rules and n's are usually

implemented by setting up a Levey-Jennings control chart or a Westgard multirule chart, and less often by a cumulative sum chart or mean and range charts.

Levey-Jennings Control Chart

Control charts were first introduced into the clinical chemistry laboratory by Levey and Jennings in 1950.[56] They demonstrated how the industrial control procedures developed by Shewhart[86] could be used with the mean and range of duplicate measurements from clinical chemical methods. In an alternate chart, single control values are plotted directly. This "single-value" chart was adopted by most laboratories because data calculations were not required before plotting the control results. Today, this single-value chart is commonly known as a "Levey-Jennings" chart, even though Levey and Jennings recommended plotting the mean and range of replicate measurements.

To use a Levey-Jennings control chart, follow these steps:

1. Analyze samples of the control material by the analytical method to be controlled on at least 20 different days. Calculate the mean and standard deviation for those results.
2. Construct a control chart either manually on graph paper or electronically using graphical software. Label the *y*-axis "control value" and set the range of concentrations to include the mean ±4*s*. Draw horizontal lines for the mean and the upper and lower control limits. Set the control limits as the mean ±3*s* when the number of control observations, *n*, is 2 or greater. When *n* is 1, control limits may be set as the mean ±2*s*. (See following discussion of performance characteristics.) Label the *x*-axis in terms of time, using day, run number, control observation number, or whatever is most appropriate for recording the relative time of the control observations.
3. Introduce control specimens into each analytical run, record the values, and plot each value on the control chart.
4. When the control values fall within the control limits, interpret the run as being "in control" and report the patient results. When a single control value exceeds the control limits, stop the method; *do not* report patient results. Inspect the method to determine the cause for the errors. Resolve the problem, then repeat the entire run—specimens and control samples. Determine control status for the new run in the same manner.

An example of a Levey-Jennings chart is shown in Figure 19-12, where control limits have been set as the mean ±3*s*. Power functions for a Levey-Jennings chart having 3*s* control limits, or a 1_{3s} control rule, are shown in Figure 19-13. The probability for false rejection is seen to be less than 0.05 or 5% even when *n* is very large. The probability for error detection increases as *n* increases, but for an *n* of 2 to 4, the procedure is not very sensitive for either random or systematic errors.

Figure 19-10 shows the power functions for a Levey-Jennings chart having 2*s* control limits, or the 1_{2s} control

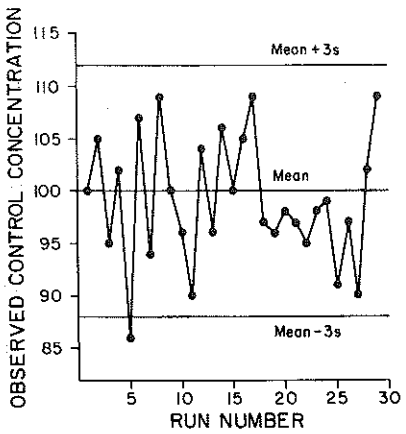

Figure 19-12 Levey-Jennings control chart having control limits set as the mean ±3 s. Concentration is plotted on the *y*-axis versus time (run number) on the *x*-axis.

rule. Observe that the *y*-intercept increases rapidly as *n* increases. The probabilities for false rejection are as follows: $n = 1$, 0.05; $n = 2$, 0.09; $n = 4$, 0.18; $n = 8$, 0.33; $n = 12$, 0.46; and $n = 20$, 0.64. Because probabilities for false rejection greater than 0.05 or 5% are not desirable, the use of the 1_{2s} rule is limited to the case where $n = 1$.

In practice, the 1_{2s} rule has been widely used with a higher *n*. However, such use causes a false rejection problem that may compromise the usefulness of the control procedure. There is no easy way to tell whether the rejection signal is due to the background random error (false rejection) or whether an additional error has occurred (true rejection). This difficulty has led to a more qualitative interpretation of the control results and often to routine repetition of the control measurements (and sometimes patient sampling) whenever a control value exceeds a 2*s* limit. When the second or repeated control value is observed to be outside the 2*s* control limits, this provides evidence for a true rejection, and problem-solving procedures should be started.

A similar false rejection problem arises when multichannel instrument systems are controlled using the 1_{2s} rule on each of several channels. For one control material being analyzed by 4, 8, 12, and 20 channels, the chances that the control value on at least one channel exceeds its 2*s* limits are 18%, 33%, 46%, and 64%, respectively. Such a high rate of values exceeding the control limits may cause the same percentage of work to be routinely repeated, obviously compromising the efficiency of the laboratory and increasing its costs.

It is important to recognize the seriousness of the false rejection problem and its relationship to the control limits that are chosen for the Levey-Jennings chart. These false rejections are in effect an inherent property of the control procedure. They occur because of the control limits that have been selected, not because of any problems with the analytical method. Therefore the use of 2*s* control limits cannot be generally recommended. With the use of 3*s* control limits,

the false rejection problem is eliminated, but unfortunately error detection is also reduced.

Westgard Multirule Chart

The "multirule" procedure developed by Westgard and associates[113] uses a series of control rules for interpreting control data. The probability for false rejections is kept low by selecting only those rules whose individual probabilities for false rejection are very low (0.01 or less). The probability for error detection is improved by selecting those rules that are particularly sensitive to random and systematic errors. The procedure requires a chart having lines for control limits drawn at the mean ±1 *s*, 2 *s*, and 3 *s*, and is adapted to existing Levey-Jennings charts by the addition of one or two sets of control limits.

The following control rules are used:

Rule	Description
1_{2s}	One control observation exceeding the mean ±2 *s* is used only as a "warning" rule that initiates testing of the control data by the other control rules.
1_{3s}	One control observation exceeding the mean ±3 *s* is a rejection rule that is primarily sensitive to random error.
2_{2s}	Two consecutive control observations exceeding the same mean plus 2 *s* or mean minus 2 *s* limit is a rejection rule that is sensitive to systematic error.
R_{4s}	One observation exceeding the mean plus 2 *s* and another exceeding the mean minus 2 *s* is a rejection rule that is sensitive to random error.
4_{1s}	Four consecutive observations exceeding the mean plus 1 *s* or the mean minus 1 *s* is a rejection rule that is sensitive to systematic error.
$10_{\bar{x}}$	Ten consecutive control observations falling on one side of the mean (above or below, with no other requirement on size of the deviations) is a rejection rule that is sensitive to systematic error.

The use of the multirule procedure is similar to the use of a Levey-Jennings chart, but the data interpretation is more structured. To use the multirule procedure, follow these steps:

1. Analyze samples of the control material by the analytical method to be controlled on at least 20 different days. Two different materials having appropriate concentrations are recommended, but a single material can be used. Calculate the mean and standard deviation for the results for each control material being used.
2. Manually or electronically construct a control chart for each of the control materials being used. The observed concentration or control value should be plotted on the *y*-axis, setting the range of concentrations to include the mean ±4 *s*. Draw horizontal lines for the mean, the mean ±1 *s*, the mean ±2 *s*, and the mean ±3 *s*. It may be desirable to use different colors for these lines, perhaps green, yellow, and red for the 1 *s*, 2 *s*, and 3 *s* limits, respectively. The *x*-axis should be scaled for time, day, or run number, and labeled accordingly.
3. Introduce two control specimens into each analytical run, one for each of the two concentrations when two different materials have been selected. Record the control values and plot each on its respective control chart.
4. When both control observations fall within the 2*s* limits, accept the analytical run and report the patient results. When one of the control observations exceeds a 2*s* limit, hold the patient results. Inspect the control data using the 1_{3s}, 2_{2s}, R_{4s}, and $10_{\bar{x}}$ rules. When any one of these rules indicates the run is out of control, reject the analytical run and do not report the patient results. When all of these rules indicate that the run is in control, accept the analytical run and report the patient results.

5. When a run is out of control, determine the type of error occurring based on the control rule that has been violated. Look for sources of that type of error. Correct the problem, then reanalyze the entire run including both control and patient samples.

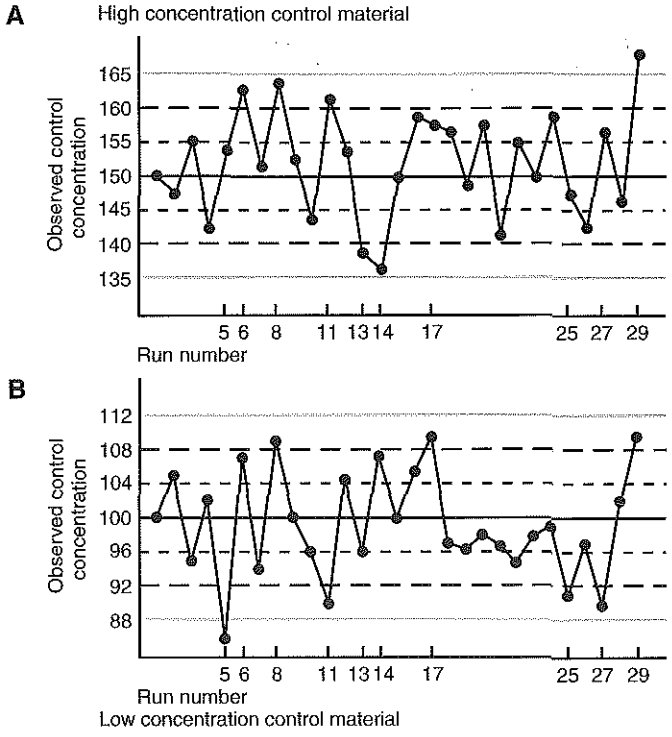

Figure 19-14 Westgard multirule control chart having control limits drawn at the mean ±1 s, 2 s, and 3 s. Concentration is plotted on the y-axis versus time (run number) on the x-axis. **A,** Chart for high-concentration control material. **B,** Chart for low-concentration control material. *(From Westgard JO, Barry PL, Hunt MR, Groth T. A multi-rule Shewhart chart for quality control in clinical chemistry. Clin Chem 1981;27:493-501.)*

An example application of the multirule procedure is shown in Figure 19-14, where the top chart is for a high-concentration control material and the bottom chart is for a low-concentration material. Table 19-2 summarizes the interpretation of the charted data, providing the run number, the accept and/or reject decision, control rules violated, and the type of error suspected based on the rule violations. It is important to note that the R_{4s} rule is applied only within a run, so that between-run systematic errors are not wrongly interpreted as random errors. However, the rule may be applied "across" materials, meaning that one of the observations can be on the low material and the other on the high material, as long as they are within the same run. On the other hand, note that the 2_{2s}, 4_{1s}, and $10_{\bar{x}}$ rules can be applied across runs and materials. This effectively increases n and improves the error detection capabilities of the procedure.

Power functions for the multirule procedure are shown in Figure 19-15 for n from 2 to 6. The probability for false rejection will be much lower at these n's than for the Levey-Jennings chart having 2s control limits. However, the false rejections do increase as n increases, limiting n to a maximum of 4 to 6. For larger n's, it would be necessary to modify the procedure by eliminating the R_{4s} rule, or by replacing this approximate range rule with an exact range rule (see discussion of Shewhart range procedure later in this chapter).

Comparison of the probability for error detection between the multirule procedure and the Levey-Jennings chart having 3s limits shows improved error detection for the multirule procedure. The R_{4s} rule improves the detection of random error and the 2_{2s}, 4_{1s}, and $10_{\bar{x}}$ rules improve the detection of systematic error. Elimination of the $10_{\bar{x}}$ rule does not cause much loss in error detection but does considerably reduce the amount of control data that must be inspected; thus the simplification may make the multirule procedure easier to use. The 4_{1s} rule could possibly be elim-

TABLE 19-2 Interpretation of Example Control Data Using the Westgard Multirule Procedure

	Decision on Run		Control Rule Violated					Type of Error

inated to further simplify the procedure, but this would be at an appreciable loss in power for detecting systematic errors.

Cumulative Sum (Cusum) Control Chart

The single-value control charts discussed in the previous sections provide a display of the differences between the observed values and the expected mean. Control rules, such as 2_{2s}, 4_{1s}, and $10_{\bar{x}}$ provide one way of determining when these successive differences no longer appear to be random (too many in a row on one side of a limit). A more exact and quantitative method is the cumulative sum control procedure or cusum chart.

TABLE 19-3 Example Cusum Calculations and Tabular Record for V-Mask Cusum Chart (for Control Material with $\bar{x} = 100$, $s = 5.0$)

Control Observation Number	Control Value	d_i	CS_i
1	110	+10	+10
2	100	0	+10

13	110	+10	+55
14	107	+7	+62
15	107	+7	+69
16	107	+7	+76

To set up a cusum chart, follow these steps:

1. Analyze the control material by the analytical method to be controlled on at least 20 different days, and calculate the mean and standard deviation of those results. (This is the same as the initial step required for a Levey-Jennings chart or for a multirule chart.)
2. Manually or electronically construct a control chart. Label the *y*-axis "cusum." Draw a horizontal line at the midpoint of the *y*-axis to represent a cusum of zero. Set the range of values above and below to be about 10 times the standard deviation. Label the *x*-axis in terms of time, using day, run number, control observation number, or whatever is most appropriate for recording the relative time of the control observation.
3. Introduce control specimens into each analytical run and record the value obtained.
4. Calculate the difference between the value and the expected mean. Obtain the cusum by adding this difference to the cumulative sum of the previous differences. Plot the cusum on the control chart and inspect the plot.
5. Interpret the charted data by evaluating the slope of the cusum line. A steep slope suggests that a systematic error is present and that the run is out of control.

Example calculations are shown in Table 19-3. These cusum values are plotted versus observation number in Figure 19-16. When control values scatter on both sides of the mean, giving both positive and negative differences, the cusum will alternate in sign, and the plotted values will wander back and forth across the zero line on the control

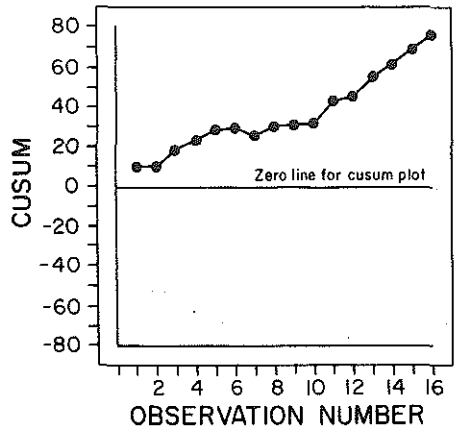

Figure 19-16 V-mask cumulative sum control chart (e.g., data in Table 19-4). The cumulative sum of the differences from the mean is plotted on the *y*-axis versus time (control observation number) on the *x*-axis.

chart. When the control values fall mostly on one side of the mean so that most of the differences have the same sign, the cusum value increases in magnitude, and the plotted values will move away from the zero line of the control chart.

It is more difficult to judge the control status from cusum charts than from Levey-Jennings or multirule charts. The approach that has been used most extensively is to make the judgment based on the slope of the cusum line. In industry, this has often been done by constructing templates having a V-shaped section removed from a rectangular sheet of clear plastic. This V-shaped cutout establishes the angle that is the control limit and gives the technique its name of "V-*mask*" *cusum*. The apex of the V-mask is positioned on the control chart at a specified distance in front of the most recent cusum observation. If all of the plotted values are contained within the angle of the V-mask, the method is judged to be in control. If any of the plotted values fall outside the angle of the V-mask, the method is judged to be out of control. Although this technique for interpreting cusum data is very objective, V-mask overlays have not been very widely used or recommended for clinical laboratories. Instead, interpretation has been based on visual inspection and on judgment of the angle of the cusum line, sometimes aided by use of special graph paper having an underlying pattern of 45° angles (∠∠∠∠∠∠∠.) across the chart. When using this special graph paper, the convention has been to scale the graph so that a change of $2s$ on the y-axis is the same distance between two points on the x-axis. The 45° angle then represents the slope expected when the observed mean is approximately $2s$ from the expected mean.

An alternative way of interpreting cusum data is to use a numerical limit for the cusum value itself, a technique known as *"decision limit" cusum*. Particular decision limit schemes are characterized by two parameters: k, a factor for calculating the threshold, and h, a factor for calculating the decision limit or control limit. The cusum calculations do not start until a control value exceeds a certain threshold

TABLE 19-4 Example Cusum Calculations and Tabular Record for Decision Limit Cusum (for Control Material with $\bar{x} = 100$, $s = 5.0$; for Control Chart with $k_u = 105$, $k_l = 95$, $h_u = 13.5$, $h_l = 13.5$)

Control Observation Number	Control Value	d_i	CS_i	Comment

above (k_u) *or below* (k_l) *the expected mean* ($\bar{x}$). *Once* exceeded, the differences from the threshold are calculated and summed for successive observations to provide the cusum. This process continues until the cusum either exceeds the upper and lower control limits (h_u and h_l) and the method is judged out of control, or until the cusum changes sign, in which case the cusum calculation is stopped and the method judged to be in control. An example of the cusum calculations for the decision limit technique is given in Table 19-4.

These example data are plotted in Figure 19-17. One advantage of the decision limit cusum chart is that it has horizontal lines for control limits, permitting the cusum chart to be interpreted in a manner similar to a Levey-Jennings chart. This form of interpretation requires less experience and judgment, thus making possible more consistent interpretation when many analysts use the control procedure. Another advantage of the decision limit technique is that it can be implemented using only tabular operations (without charting), thus making it very easy to program for computerized handling of control data.

Although interpretation is easier and more objective, selecting the threshold and control limits is somewhat difficult. This selection is done with the aid of nomograms,

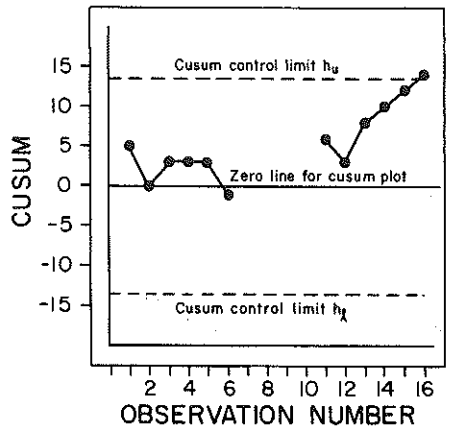

Figure 19-17 Decision limit cumulative sum control chart (e.g., data in Table 19-5). The cumulative sum of the differences from the threshold is plotted on the *y*-axis versus time (control observation number) on the *x*-axis.

which are quite complicated to understand and use, and therefore it is initially perhaps best to use one of the decision limit schemes recommended in the clinical chemistry literature.[120] For manual implementation, set the threshold at the $x \pm 1.0s$ and the control limits at $2.7s$. For computer implementation, set the threshold at the $x \pm 0.5s$ and the control limits at $5.1s$. This latter procedure will be sensitive to smaller errors because of the choice of the lower threshold. However, the charting is not as convenient when performed manually, particularly when the cusum is used in combination with the 1_{3s} control rule to provide better detection of random errors.[120]

When compared with the Levey-Jennings chart with $3s$ limits, the cusum procedure provides better detection of systematic errors but less sensitivity for random errors. Because of the low sensitivity to random errors, cusum should not be used alone, but rather should be included with a Levey-Jennings procedure on a combined chart[120] or used as a separate chart along with a Levey-Jennings chart. Performance is similar to the multirule procedure for low n's, at least as far as detecting systematic errors. However, the multirule procedure is more sensitive to random errors because of the added R_{4s} rule.

Shewhart Mean and Range (or Standard Deviation) Control Charts

Statistical quality control charts were first introduced in industry during the 1930s by Shewhart,[86] who recommended obtaining a group of control measurements, determining the average and standard deviation of the group, then plotting the average on an "*x*-bar" or mean chart and the standard deviation on an *S*-chart. For n's less than 10, the *S*-chart is usually replaced by a "range" or *R*-chart on which is plotted the range, or difference between the highest and lowest observations of the group.

To set up mean and range charts, initial estimates must be obtained for the mean and standard deviation, or the

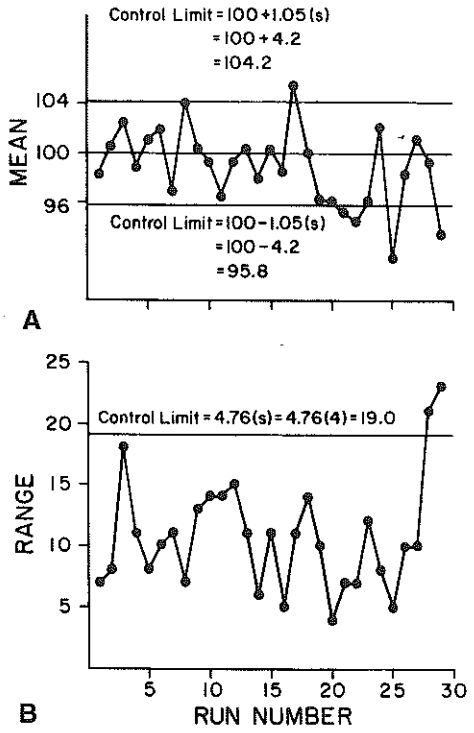

Figure 19-18 Shewhart mean and range control charts. **A,** Mean chart. **B,** Range chart.

mean and average range, as determined for the control material to be used and the analytical method to be controlled. Control limits for the charts are calculated using appropriate factors (see Table 17-3 in the 3rd edition of this textbook).[123] A group of control measurements is then collected in each analytical run, and the mean and range (or standard deviation) are calculated and plotted. An example set of data is given in Table 19-5 and plotted on the mean and range charts in Figure 19-18.

Implementation by Use of the Z and Chi-Square (χ^2) Tests

Charts for mean, range, and standard deviation are seldom found in clinical laboratories because of the time required for calculating the control statistics. These control procedures are probably practical only when computerized data handling is available. An easy way of implementing these procedures on computers is to employ statistical tests of significance. A *Z*-test can be used to determine whether the mean has changed from its original value, and a χ^2-test can be applied to determine whether the standard deviation has changed from its original value.

The values for Z and χ^2 are determined from the following equations:

$$Z_{obs} = \frac{\bar{x}_{obs} - \bar{x}_{exp}}{\frac{s_{exp}}{\sqrt{n}}}$$

$$\chi^2_{obs} = \frac{(s_{obs})^2(n-1)}{(s_{exp})^2}$$

TABLE 19-5 Shewhart Mean and Range Calculations and Tabular Record

where $\bar{x}_{obs}$ is the mean observed in the analytical run being tested, $\bar{x}_{exp}$ is the mean expected when the method is working properly, n is the number of control measurements in the group, s_{obs} is the standard deviation observed in the analytical run being tested, and s_{exp} is the standard deviation expected when the analytical method is in stable operation. To determine the control status of an analytical run when using the Z-test, the observed Z-value is compared with the critical Z-value for a selected probability for false rejection. The critical values are 1.96, 2.58, and 3.09 for probabilities of false rejection of 0.05, 0.01, and 0.002, respectively. When the observed Z-value is less than the critical Z-value, the run is judged to be in control. When it exceeds the critical Z-value, the run is judged to be out of control.

To determine control status using the χ^2-test, the observed χ^2-value is compared with the critical χ^2-value (see Table 17-3 in the 3rd edition of this textbook).[123] When the observed value is less than the critical value, the run is judged to be in control; when it exceeds the critical value, the run is judged to be out of control.

Alternative Calculations and Applications

Moving averages and moving standard deviations are used in industry and sometimes in clinical laboratories. With these procedures, n is chosen, measurements are collected until n is attained, and then the mean and standard deviation are calculated. With each additional measurement, the oldest measurement is dropped, the newest is added, and new estimates of the mean and standard deviation are obtained after each new control measurement, rather than waiting for new groups of n measurements. Parvin[69] has proposed the use of a multimean rule that combines the means of control values observed in consecutive runs. Similar updated means and standard deviations are obtained from exponential smoothing, a calculation procedure that provides an average that weighs recent observations more heavily than older observations.[118] The "smoothed mean" is sensitive to trends that are just beginning to develop, and therefore it is often referred to as a *trend analysis procedure.* The calculations are too complicated to be implemented manually, but the availability of computers makes these calculations feasible in clinical laboratories.

Power functions for mean (or *Z*-test), range, and χ^2 (or standard deviation) control procedures, when compared with those for previous control procedures, show higher probabilities for error detection, particularly at larger n's. The probability for false rejection can be set at a suitably low level by proper choice of control limits. Thus these control procedures appear to offer better performance characteristics than single-value control charts because they have higher error detection and lower false rejection as *n* increases.

The use of mean and standard deviation control procedures (or related procedures) to monitor accuracy and precision is a direct extension of the practices of method evaluation, the mean being used to monitor systematic error and the standard deviation to monitor random error. This relationship helps explain why control procedures having n's from 1 to 4 have relatively low power or error detection capability. Not surprisingly, it is more difficult to estimate precision and accuracy using quality control procedures with n's of 1 to 4 than with method evaluation procedures using n's of 20 to 40. For low ns, all control procedures have relatively low power. As *n* increases, power will increase, particularly for procedures using mean, range, *S*-charts, *Z*-tests, and χ^2-tests, moving averages and moving standard deviations, and trend analysis. Future practices in statistical quality control in clinical laboratories will undoubtedly make greater use of these procedures.

The integration of powerful computer hardware and software into analytical systems has made it practical to use complicated control procedures on a routine basis in clinical laboratories. Calculations on control data, once properly programmed, are performed quickly and without mistakes. Graphical displays can be generated, with color added to aid the interpretation of control data. Specific control rules are programmed to provide "accept" and "reject" signals or printouts. Records are maintained to document instrument changes, preventive maintenance, and control problems. Monthly summary statistics and quality control reports are generated. Many of these features, along with many of the statistical control procedures that have been described, are found in microcomputer quality control programs that are commercially available today.

CONTROL OF ANALYTICAL QUALITY USING PATIENT DATA

QC mechanisms based on patient data provide additional information useful in monitoring the quality of laboratory analyses. These procedures are often time consuming and generally are not sensitive enough to serve as the only means of QC. However, many of the control problems detected with these techniques may not be evident with conventional QC systems. A quality assurance program should make appropriate use of "patient data procedures," and both individual and multiple patient results have been used for QC purposes.

INDIVIDUAL PATIENT RESULTS

The patient test results are the final product of most laboratory procedures, and the monitoring of these results is the most direct form of QC. Unfortunately, procedures for monitoring results are not very sensitive and have low probabilities for error detection. The most effective procedure is the clinical correlation of test results with other information related to the patient, especially surgical findings, response to therapy, and autopsy data. Less sensitive but easier to implement are comparisons with previous test values and correlation with related test results. The easiest procedure is the comparison of test results with physiological or probabilistic limits.

Clinical Correlation

Operationally, it is impractical for high-volume, core laboratories to correlate all test results with the clinical status of the patients. In general, the clinicians ordering the tests are in a better position to evaluate the appropriateness of test results. However, clinicians often order a test because they are uncertain of the exact clinical status of their patient and base their diagnoses heavily on the laboratory test results. In such cases, it is circular reasoning to correlate clinical diagnoses with laboratory test results. Clinical correlation studies are best done retrospectively when laboratory test results are directly related to other evidence, such as surgical findings. Unfortunately, most laboratory tests do not correlate perfectly with disease states, and one must evaluate multiple cases before determining the diagnostic efficiency of a given test (as discussed further in Chapter 14). In an individual patient, clinical correlation can identify impossible or highly unlikely test results that cannot be flagged in the laboratory, such as a normal serum bilirubin concentration in a highly jaundiced patient. Clinicians should be encouraged to report these discrepancies to the laboratory, and a mechanism should be available to follow up these problems. Also, after using a test for a period of time, many clinicians can detect alterations in test results, and although this is not reliable for documenting problems, informal discussions with clinicians frequently using the test can aid in identifying aspects of laboratory tests that should be further investigated.

A focus on linking laboratory tests to patient care outcomes (see Chapter 13) requires an integrated healthcare system in which all processes are operating properly.[38,131] This integrated system includes the correct assessment of the patient's problem, ordering of the correct tests, accurate and timely analytical performance, correct interpretation of the test results, and implementation of appropriate clinical actions that produce the expected response in the patients. Obviously this complete cycle is subject to numerous variables, which traditionally are outside of the control of the laboratory. However, under managed care there is a strong incentive to ensure that the complete system is working. All patients do not respond the same; therefore the responses of multiple patients with similar disorders must be monitored.

Some examples of this approach are the linkage of adverse outcomes of inappropriate anticoagulation (stroke, myocardial infarct, or death within 6 days) to the measurement of prothrombin times and the linkage of adverse effects of digoxin therapy (death or hospitalization caused by insufficiency, overdose, or drug reaction) with the measurement of digoxin.[129]

Correlation with Other Laboratory Tests

As in clinical correlation, there are a limited number of situations in which a single test result is plausible, but the combination of several test results is impossible or very unlikely. If the tests involved in these comparisons are performed at the same time, one often can identify errors and correct problems before reporting the test results to the clinicians. Even though very few tests have exact clinical relationships and one often must consider statistical percentages rather than the results of a single patient to identify malfunctions, several relationships provide some possibilities for monitoring an individual patient's results, at least for purposes of initiating further review:

1. *Blood typing.* There is a close association between the ABO blood antigens on erythrocytes and isoantibodies found in plasma. Exceptions are found in patients recently transfused with whole blood.
2. *Anion gap.* To maintain electrical neutrality, the sum of the charges of anions in a blood sample must equal the sum of the charges of cations when expressed in molar concentrations. With all units in mmol/L, an anion gap (AG) can be calculated as

$$AG = (Na^+ + K^+) - (Cl^- + HCO_3^-)$$

   Values less than approximately 10 mmol/L or greater than about 20 mmol/L may indicate error. Elevated values may be found in patients with renal failure, diabetic acidosis, cardiac failure, anoxia, and other conditions (see Chapter 46). Low values occur in hypoproteinemia and with intravenous hydration. The capabilities of AG control procedures have been studied by Cembrowski and co-workers,[22] who recommend that the average AG of groups of eight or more patients be used to provide a more sensitive statistical control.
3. *Osmolar gap.* Serum osmolality can be estimated from the concentrations of a few major blood constituents and can also be measured using colligative properties (see Chapter 27).[33] The osmolar gap (OG) is defined as the measured osmolality minus the calculated osmolality or

$$OG = \text{osmolality} - \left[1.86(Na^+) + \frac{\text{glucose}}{18} + \frac{\text{urea}}{2.8} + 9\right]$$

   where osmolality is in mosm/kg, sodium is in mmol/L, and glucose and urea nitrogen are in mg/dL. The factor "9" represents the contribution of other osmotically active substances in plasma, such as K^+, Ca^{2+}, and proteins. Normally this gap is near zero. Alcohol consumption or the ingestion of toxins, such as salicylates or ethylene glycol, causes an increase.[34,132] Alterations of unmeasured electrolytes and dehydration may also increase the gap.
4. *Acid-base balance.* The Henderson-Hasselbalch equation is also used to calculate theoretical bicarbonate and total CO_2 concentrations when pH and PCO_2 are measured. Theoretical and measured results generally agree within 2.0 mmol/L.
5. *Thyroxine-TSH.* Normally, thyroxine sends a negative feedback to the pituitary and reduces the secretion of thyroid stimulating hormone (TSH). Patients with serum thyroxine concentrations above 8.0 µg/dL seldom have elevated concentrations of TSH. Exceptions occur in secondary and tertiary hyperthyroidism.

Intralaboratory Duplicates

Samples can be divided into two aliquots and analyzed, and the duplicates used for control purposes. This is a simple quality control procedure that does not require stable control materials and therefore can be used when stable materials are not available or as a supplemental procedure when stable control materials are available. The differences between duplicates are plotted on a range type of control chart that has limits calculated from the standard deviation of the differences.[110] When the duplicates are obtained from the same method, this range chart monitors only random error and thus is not adequate for ensuring the accuracy of the analytical method. When the duplicates are obtained from two different laboratory methods, then the range chart actually monitors both random and systematic errors but cannot separate the two types of errors. The interpretation becomes more difficult, particularly when there are stable systematic differences or biases between the two analytical methods. Multiplicative factors may be necessary to deal with proportional differences, and additive factors may be necessary to allow for constant differences. Interpretation of observed differences becomes more qualitative; nevertheless, this procedure still provides a useful way of monitoring the consistency of the data being generated by the laboratory.

Delta Checks with Previous Test Results

Certain errors, particularly errors in specimen identification, have been detected by comparing laboratory test results with values obtained on previous specimens from the same patient. The expected variability of test results depends on both the analyte and the time interval between determinations. Ladenson has defined delta check limits based on a 3-day interval in terms of a percentage change from the initial value.[51] His check limits for some common tests are shown in Table 19-6.

In identifying specimen-related errors, it is helpful to examine multiple test parameters, including hematological tests, because differences in a profile of test results often are more obvious and more statistically significant than are changes in individual tests. For example, in a 1979 study, the performance of several delta check methods was evaluated,

including two discriminant functions, for detecting mislabeled specimens; a false-positive rate of 5% and an error detection of about 50% for mislabeled specimens were observed.[123]

Limit Checks

A patient's test results should be reviewed to check that they are within the physiological ranges compatible with life. These limit checks are helpful for detecting clerical errors, such as transposed digits or misplaced decimal points. This checking can be combined with warning limit checks for detecting and verifying possible, but infrequently occurring, test results. These warning limits are dependent on test methodology and on the characteristics of the patient population being tested. Table 19-7 shows limits for some common tests.

TABLE 19-6 Recommended Limits for Delta Checks

Test	Delta Check Limit
Albumin	20%
Bilirubin, total	50%
Calcium, total	15%
Creatine kinase	99%
Creatinine	50%
Phosphorus	20%
Potassium	20%
Protein, total	20%
Sodium	5%
Thyroxine	25%
Urea nitrogen	50%
Uric acid	40%

Multiple Patients

Test Distribution Statistics

Statistics based on distributions of test results from large numbers of patients are useful for detecting systematic errors (shifts and drifts) but are of no value for detecting random errors (increased variability or scatter). They are useful adjuncts to the fundamental control procedures, which use stable control materials, but should not be substituted for them. Patient values include numerous sources of variation—demographical, biological, pathological, and preanalytical (see Chapter 17)[134]—in addition to the analytical variation caused by the analytical method. As a result, individual test values have too much variability to have any utility for QC; however, the mean of multiple test values or groups of patients is more stable and therefore may be useful for control purposes.

The variability of the mean test result from a group of n patients decreases proportionally to the square root of the number of determinations. The variability of the estimated mean is given by the standard error of the mean (SEM), which is equal to the standard deviation of the patient population divided by the square root of n, the number of patient measurements included in the group mean. Consider the following example, where the s of the patient values is 100 units. As n increases to 16, 25, 100, and 400, the SEM becomes 25, 20, 10, and 5 units, respectively. If the s of the analytical method was 10 units, the distribution of patients would be 10 times as large; however, if one considers the mean values of groups of 100 patients, the variability (SEM) of the group mean is approximately equal to the variability

TABLE 19-7 Recommended Ranges for Limit Checks

Test	Low Warning	High Warning
Acid phosphatase* (U/L)	0.1	10
Albumin (g/dL)	1.5	6
Alkaline phosphatase* (U/L)	5	300
Amylase* (U/L)	20	1000
Bilirubin (mg/dL)	0.2	10.0
Calcium (mg/dL)	6.5	13.0
Creatine kinase (U/L)	5	1500
Creatinine (mg/dL)	0.3	7.5
Phosphorus (mg/dL)	1.0	8.0
Potassium (mmol/L)	3.0	6.0
Sodium (mmol/L)	120	150
Urea nitrogen (mg/dL)	3	50
Uric acid (mg/dL)	1.0	12.0

Values are method dependent.
From Whitehurst P, DiSilvio TV, Boyadjian G. Evaluation of discrepancies in patients' results: An aspect of computer-assisted quality control. Clin Chem 1975;21:87-92.

observed on individual observations on stable control materials. For groups of 400 patients, the variability of the mean is half that for individual observations on the stable control material.

Changes in the means of patient populations may be caused by multiple variables (see Chapters 16 and 17). Changes in the demographic and clinical characteristics of the patients, such as the ratio of males to females, the ratio of hospitalized patients to outpatients, or the presence of many specimens from a specialty clinic can alter the mean value. Similarly, changes in preanalytical conditions,[134] such as tourniquet time and specimen storage, alter patient population means and can therefore be monitored by use of patient means. These variables are not monitored by those control procedures employing stable materials; thus the "patient mean procedures" provide additional capabilities and should be used in conjunction with other control procedures.

Statistical Methods for Monitoring Patient Means

The "mean of normals" or "average of normals" (AON) approach calls for establishing limits, usually the limits for reference values, for "trimming" the patient data.[125] Values outside these limits are eliminated from the calculations, thus reducing the response to outliers and subpopulations and also to real errors. An alternative approach has been to use the median as the control statistic, and this may be a more sensitive indicator of change than the mean. More complicated estimates have been recommended to account for hospitalized patients having slightly different test values from those of ambulatory patients. A weighted mean based on the percentage of patients in each category has greater sensitivity for error detection, particularly for measurements of the serum concentration of total protein, albumin, and calcium.

Bull's algorithm has been widely employed for online monitoring of automated hematological cell counters. Bull and colleagues[10] evaluated six statistics for monitoring erythrocyte indices: the sample mean, two moving average means, the mean of a truncated sample, the John's mean, and the median. They assessed the usefulness of these different statistics by mathematically introducing both abrupt bias changes and cyclical time changes. The moving average statistics were found to have superior error detection. The batch size used in calculating the moving average regulates the smoothing of the data. Large batch sizes not only smooth out undesired individual patient effects, but also increase the number of specimens (and time) necessary to detect instrument malfunction. A weighted moving average based on a batch size of 20 specimens was recommended. Cembrowski has developed power function graphs to provide quantitative information of both single-rule and multirule variations of Bull's algorithm.[21,57]

Control statistics based on patient data have been readily implemented in computerized laboratories.[43] However, several authors have shown that these control procedures are not as sensitive as procedures using stable reference material. All of these statistics are designed to detect systematic errors and have virtually no power for detecting random error. The relative sensitivity of these statistics for detection of systematic errors, as compared with stable reference controls, is dependent on three factors: variation of patient test values (and the test statistics derived from them), analytical variation, and the ratio of the number of specimens to the number of controls. Low patient variability, high analytical variability, and a high ratio of specimens to controls favor patient-based QC procedures. Patient test result variability depends not only on the analyte measured, but also on the population being tested. Populations consisting mainly of healthy individuals generally have lower test variability than the populations of medical specialty clinics. A quantitative study of these variables and their effects on the statistical power of procedures using patient means has been performed by Cembrowski and co-workers.[19] Smith and Kroft[89] have further evaluated the performance and relationship of AON and Bull's algorithms and have proposed an exponentially adjusted moving mean whose performance can be optimized for individual applications.

Effect of Analytical Bias on Clinical Decisions

Changes in analytical bias directly shift the distribution of the patient test values. If the elevated values on a test are associated with specific clinical actions, then the shifts in analytical bias can notably alter the number of patients having test values that exceed the action limit.[46] For example, for a serum calcium assay with an action limit of 10.1 mg/dL, an upward bias of 0.2 mg/dL changes the number of patients subjected to further investigation from 6.5% to 15.0%. Similarly, analytical shifts in other critical analytes can cause notable clinical problems, such as false elevations of prostate-specific antigen values triggering prostate ultrasound examinations and biopsies and false elevation of TSH triggering additional thyroid examinations. These small analytical shifts can have major downstream effects on healthcare costs.

Combined Use of Liquid Controls and Moving Averages of Patient Values for Quality Control Monitoring

Distributions of the measured test values have been used to supplement the traditional liquid controls for monitoring analytical bias. These patient specimen measurements generally have much larger variances than liquid controls because they contain biological, pathophysiological, and preanalytical sources of variation in addition to the analytical variation. However, if some of these sources of variation are controlled, averaging techniques often are used to generate tracking parameters, which have variations of the same order of magnitude as liquid controls. Demographic information about specific patients such as age, sex, and medical provider service area have been used to normalize the test values, resulting in smaller variances of the group means for the monitoring parameters. The larger the window size used for

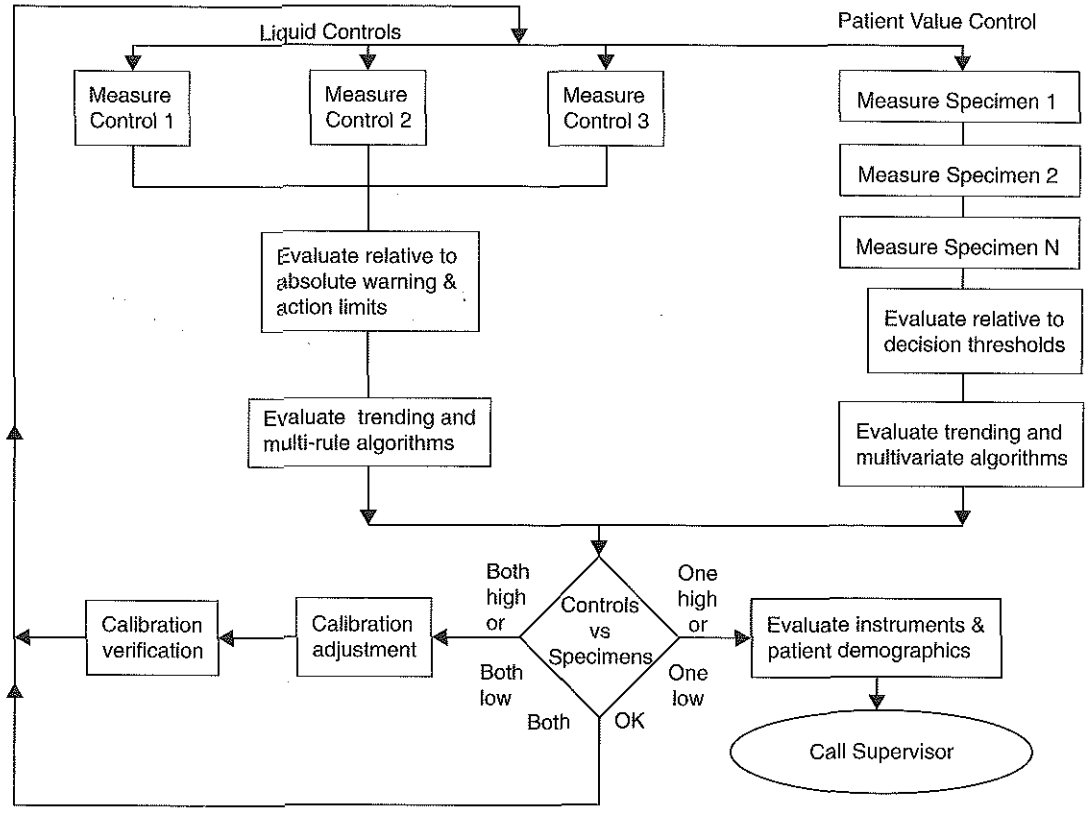

Figure 19-19 Protocol for combining liquid controls and a patient value–derived control.

averaging patient values the smaller the variance. The CV of the group mean decreases approximately proportional to the square root of the number of samples. Various statistical techniques have been used to average the patient values, such as the exponentially adjusted moving mean proposed by Smith and Kroft.[89,90] In general, there is a trade off between decreased variance versus increased time for error detection when larger numbers of patient values are used in these moving averages. For most chemistry tests, window sizes using 50 to 100 sample values often are necessary.[45] An advantage of test value distributions over liquid controls is the inclusion of preanalytical variation caused by specimen collection, transport, and storage. This allows patient value–derived parameters to detect changes in these variables in addition to changes in the analytical testing.

Figure 19-19 illustrates an algorithm for combining liquid controls with a patient value–derived parameter. The same multirule evaluation systems used for liquid controls have been used for tracking the patient value–derived QC statistic. Set points and threshold values are assigned to this derived parameter to optimize the power for error detection for systematic error. Note that the averaging algorithms used to generate these derived parameters average out random errors, so these derived parameters are not useful for detecting random errors. As illustrated in the figure, this combined control protocol is most accurate when both the liquid control and the patient-derived control move in the same direction (both high or both low). When the controls move discordantly, further investigation is necessary to define if the problem is related to instability of the liquid controls, changes in the patient characteristics (such as many sick patients seen at one time), preanalytical test changes, or other causes.

Clinical Correlation Studies

Retrospective correlation studies relating laboratory test results to surgical findings or therapeutic changes in patients are effective mechanisms for long-term QC. Two separate patient populations are necessary to efficiently monitor both false-positive and false-negative laboratory test results. To monitor false-positive results, the records of patients with positive results should be randomly sampled and reviewed for confirmatory evidence of disease. For many laboratory tests, substantial medical follow-up is necessary to confirm or refute test results, and, unfortunately, medical records often do not contain this information. Again, stated diagnoses cannot be used to confirm laboratory test results, since the laboratory test results may have been the primary evidence for the diagnosis. To monitor false-negative results, the records of patients with objective clinical confirmation of the disease should be randomly sampled and reviewed. Examples of objective confirmation are surgical discovery of a tumor, improvement in physical signs and symptoms following pharmacological or surgical therapy, and autopsy

findings. It is difficult to obtain unbiased record selection, because test results often alter clinical decisions regarding surgery or therapy. There is less selection bias in autopsy data, but the disease process generally is more advanced in these patients.

EXTERNAL QUALITY ASSESSMENT AND PROFICIENCY TESTING PROGRAMS

All of the control procedures described earlier in the chapter have focused on monitoring a single laboratory. These procedures constitute what is called *internal quality control*[108] to distinguish them from procedures used to compare the performance of different laboratories, the latter being known as *external quality assessment.* The two are complementary activities, internal QC being necessary for the daily monitoring of the precision and accuracy of the analytical method, and external quality assessment being important for maintaining the long-term accuracy of the analytical methods.[15,17]

In practice, internal QC procedures only detect changes in performance between the present operation and the "stable" operation that was characteristic during the baseline period when the analytical method was thought to be operating properly. Although the procedures detect systematic and random errors, the only systematic errors detected are those changes from the original baseline. If the method actually had some undetected systematic errors during the baseline period, those systematic errors would be included in the mean that was used to calculate the control limits for the procedure. Thus only systematic changes from this original mean will be detected by internal QC procedures.

Initial method evaluation studies are essential to ensure that systematic errors are not present before the baseline period and the determination of the mean and the control limits. The accuracy of the method should be initially established by comparison with other analytical methods (and recovery and interference studies) and should continue to be monitored by comparison with other analytical methods. Ongoing comparison-of-methods studies are desirable to ensure that systematic errors do not slowly increase and go undetected by internal QC procedures. These ongoing comparison studies are provided by the external QA programs, which in turn form the basis for proficiency testing programs.

EXTERNAL QUALITY ASSESSMENT

Several external QA programs are available to laboratories, some sponsored by professional societies and others by manufacturers of control materials. The basic operation of these programs involves having all the participating laboratories analyze the same lot of control material, usually daily as part of the internal QC activities. The results are tabulated monthly and sent to the sponsoring group for the data analysis. Summary reports are prepared by the program sponsor and are distributed to all participating laboratories. This reporting takes time for processing all the data from a large number of laboratories; thus the data analysis is not available in real time and is useful only for monthly reviews and periodic problem-solving activities. However, with advances in telecommunications and the arrival of the World Wide Web, real-time external QC is a possibility.

The reports often include extensive data analysis, statistical summaries, and plots. The mean of all results or the mean of results from peer laboratories (those performing the test with similar methods) is taken as the target value and is used for comparison with the individual laboratory's result. Different programs do this in different ways. For example, the statistical significance of any difference between an individual laboratory's observed result and the group mean can be tested by use of the *t*-test. When the difference is significant, the laboratory is alerted that its results are biased compared with the results of most of the other laboratories. Another approach is to divide the difference by the overall standard deviation of the group, and then to express the difference in terms of the number of standard deviations

$$\text{SDI} = \frac{\text{Laboratory Result} - \text{Group Mean}}{\text{Group } s}$$

where SDI is the abbreviation for standard deviation interval or index, and Group *s* is the standard deviation for the group or a selected subset of the group. Differences greater than 2 or 3 indicate that a laboratory is not in agreement with the rest of the laboratories in the program. These calculations reduce all the test results to the same values, which makes it possible to interpret the data without reference to the exact mean and *s* for each analytical method. For example, a value of +2.0 has the same meaning for any test, indicating that the value is 2 *s* above its target mean.

Additional information about the nature of the systematic error is obtained when there are two different control materials analyzed by each laboratory. For example, the laboratory's observed mean for material A is plotted on the *y*-axis versus its observed mean for material B on the *x*-axis; these graphs are called *Youden* plots.[133] Ideally the point for a laboratory should fall at the center of the plot. Points falling away from the center but on the 45° line suggest a proportional analytical error. Points falling away from the center but not on the 45° line suggest either an error that is constant for both materials or an error that occurs with just one material.

The report may also include Levey-Jennings plots of the data, but because this information is not available in real time, it does not effectively serve the purposes of internal QC. Blank control charts that are set up for each analyte and each control material save the laboratory the time that is required when these charts are prepared manually.

The operation of external QA programs is greatly improved by using a PC and appropriate software. Operationally the external comparison is more quickly performed using the PC as a terminal for transmitting data via the

Internet to the central computer. The processing of the data to compare the results from the many different laboratories is then performed and the reports returned to the laboratory. Since the individual control observations are entered into the PC, the control data are then immediately tested by internal control procedures to determine control status. Thus in practice, the PC integrates the internal and external procedures into a more efficient program for QA.

Proficiency Testing and Laboratory Accreditation

Proficiency testing (PT) programs are a type of external quality assessment in which simulated patient specimens made from a common pool are analyzed by the laboratories enrolled in the program. The results are returned to a central facility and evaluated to determine the "quality" of each laboratory's performance. Government and licensing agencies are increasingly using PT as an objective method for accrediting laboratories thereby giving them official authorization to operate.[84]

An example of using PT for such a purpose is the U.S. government's mandate that clinical laboratories be accredited and licensed. Historically, this developed after a series of newspaper articles were published that focused on laboratory quality problems and led to a determined effort by the U.S. government to protect patients' interests and the public welfare.[7,8] In 1988 the U.S. Congress subsequently revised the Clinical Laboratory Improvement Act of 1967 (CLIA '67) and passed the Clinical Laboratory Improvement Amendment (CLIA '88); it mandates PT as a major part of the laboratory accreditation process.[73,100] The implementation rules for this legislation have been evolving, with the final legislative rule being published on January 24, 2003.[99] Additional interpretative guidelines were published by the Centers for Medicare and Medicaid Services (CMS) in January 2004 in the form of the State Operations Manual. Appendix C of that document refers specifically to guidelines for laboratories and laboratory testing services.[1]

The initial CLIA '88 regulations focused primarily on the analytical process. However, it was later stressed that the quality of the "total testing process" must be monitored in addition to the precision and accuracy of the analytical phase.[70,72,78,130] Thus as mentioned earlier in this chapter, current QA programs that monitor only the analytical phase of the total process have to be expanded to include both the preanalytical (see Chapter 17) and postanalytical phases (www.westgard.com/essay34).

CLIA requires all U.S. laboratories to register with the government and to identify the tests they perform. Certain tests are "waived," meaning that any laboratory can perform those tests as long as they follow the manufacturers' directions. There are no other requirements for quality management of those tests. Laboratories that perform "nonwaived" tests are subject to the complete CLIA regulations and must be inspected periodically by the government or by certain professional organizations that are deemed to have standards at least as stringent as the CLIA requirements. Two such organizations are the College of American Pathologists (CAP) and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). The CLIA implementation rules and interpretative guidelines outline the criteria for acceptable performance in laboratory inspection and accreditation.

The CLIA requirements cover several broad classes: (1) Subpart J. Facility Administration; (2) Subpart K. Quality Systems; (3) Subpart M. Personnel; and (4) Subpart Q. Inspection. The final rule dealt mainly with changes to the subpart on Quality Systems, with particular attention to preanalytical, analytical, and postanalytical systems. It places increased emphasis on having quality systems to monitor preanalytical and postanalytical processes, yet the biggest impact of the final rule is on analytical quality assessment and analytical quality systems.[115]

In general the performance characteristics of PT programs for detecting bias and imprecision are evaluated using methods similar to those listed for assessing internal QC.[52] A commonly used evaluation criterion has been the comparison of PT test results with those of peer groups, considering all values that exceed 2 SD to be "unacceptable." This rule fails to detect many of the laboratories that have poor performance, especially those that have precision problems.[27] The initial CLIA '88 proposal called for the PT of two specimens four times per year, but the final rule expanded this to the study of five samples three times per year so as to improve the capability of detecting "unacceptable" performance. The criterion for PT failure is two of five incorrect results on two of three consecutive PT surveys.

CLIA '88 proposed criteria group laboratory tests into "specialty" and "subspecialty" categories and specify representative tests to be monitored in each category.[70,100] To be totally "successful" in a given category, a laboratory must produce correct results on four out of five specimens for each of the analytes in that category and have an overall score of at least 80% for three consecutive challenges. If there are more than two incorrect results for any analyte, the laboratory is considered "on probation." If a laboratory has two or more incorrect results for any analyte or has an overall score less than 80% on two of three consecutive surveys, it is classified as "suspended" and must cease testing all analytes in that specialty category until it is reinstated.

The CLIA regulations have established fixed limits (either percentages or absolute values from target) for evaluating PT performance. These test categories and limits are shown in Table 19-8. The target values for these analytes will be established by the agencies implementing the PT programs under the federal guideline[100] that states: "Target value means either the mean of all responses after removal of outliers (those responses greater than 3 standard deviations from the original mean) or the mean established by definitive or reference methods acceptable for use in the National Reference System (NRS) for the Clinical Laboratory by the NCCLS. In instances in which definitive or reference methods are not

TABLE 19-8 HCFA/CLIA Proficiency Testing Criteria for Acceptable Performance

Analyte or Test	Acceptable Performance
Routine Chemistry	
Alanine aminotransferase	Target value ± 20%
Albumin	Target value ± 10%
Alkaline phosphatase	Target value ± 30%
Amylase	Target value ± 30%
Aspartate aminotransferase	Target value ± 20%
Bilirubin, total	Target value ± 0.4 mg/dL or ± 20% (greater)
Blood gas PCO_2	Target value ± 55 mm Hg or ± 8% (greater)
Blood gas pH	Target value ± 0.04
Blood gas PO_2	Target value ± 3 SD
Calcium, total	Target value ± 1.0 mg/dL
Chloride	Target value ± 5%
Cholesterol, high-density lipoprotein	Target value ± 30%
Cholesterol, total	Target value ± 10%
Creatine kinase	Target value ± 30%
Creatine kinase isoenzymes	MB elevated (presence or absence) or target value ± 3 SD
Creatinine	Target value ± 0.3 mg/dL or ± 15% (greater)
Glucose	Target value ± 6 mg/dL or ± 10% (greater)
Iron, total	Target value ± 20%
Lactate dehydrogenase (LD)	Target value ± 20%
LD isoenzymes	LD 1/LD 2 positive or negative or target value ± 30%
Magnesium	Target value ± 25%
Potassium	Target value ± 0.5 mmol/L
Sodium	Target value ± 4 mmol/L
Total protein	Target value ± 10%
Triglycerides	Target value ± 25%
Urea nitrogen	Target value ± 2 mg/dL or ± 9% (greater)
Uric acid	Target value ± 17%
Endocrinology	
Cortisol	Target value ± 25%
Free thyroxine	Target value ± 3 SD
Human chorionic gonadotropin	Target value ± 3 SD or positive or negative
T_3 uptake	Target value ± 3 SD
Triiodothyronine	Target value ± 3 SD
Thyroid stimulating hormone	Target value ± 3 SD
Thyroxine	Target value ± 20% or 1.0 μg/dL (greater)
Toxicology	
Alcohol, blood	Target value ± 25%
Blood lead	Target value ± 10% or ± 4 μg/dL (greater)
Carbamazepine	Target value ± 25%
Digoxin	Target value ± 20% or 0.2 ng/mL (greater)
Ethosuximide	Target value ± 20%
Gentamicin	Target value ± 25%
Lithium	Target value ± 0.3 mmol/L or ± 20% (greater)
Phenobarbital	Target value ± 20%
Phenytoin	Target value ± 25%
Primidone	Target value ± 25%
Procainamide (and metabolite)	Target value ± 25%

From the U.S. Department of Health and Human Services: Clinical Laboratory Improvement Amendments of 1988; Final Rules and Notice. 42 CFR Part 493. The Federal Register 1992;57:7188-288.

Continued.

TABLE 19-8 HCFA/CLIA Proficiency Testing Criteria for Acceptable Performance—*Continued*

Analyte or Test	Acceptable Performance
Toxicology—Cont'd	
Quinidine	Target value ± 25%
Theophylline	Target value ± 25%
Tobramycin	Target value ± 25%
Valproic acid	Target value ± 25%
Hematology	
Cell identification	90% or greater consensus on identification
White cell differentiation	Target ± 3 SD based on percentage of different types of white cells
Erythrocyte count	Target ± 6%
Hematocrit	Target ± 6%
Hemoglobin	Target ± 7%
Leukocyte count	Target ± 15%
Platelet count	Target ± 25%
Fibrinogen	Target ± 20%
Partial thromboplastin time	Target ± 15%
Prothrombin time	Target ± 15%
General Immunology	
α_1-antitrypsin	Target value ± 3 SD
α-fetoprotein	Target value ± 3 SD
Antinuclear antibody	Target value ± 2 dilution or positive or negative
Antistreptolysin O	Target value ± 2 dilution or positive or negative
Anti-human immunodeficiency virus	Reactive or nonreactive
Complement C3	Target value ± 3 SD
Complement C4	Target value ± 3 SD
Hepatitis (HBsAg, anti-HBc, HBeAg)	Reactive (positive) or nonreactive (negative)
IgA	Target value ± 3 SD
IgE	Target value ± 3 SD
IgG	Target value ± 25%
IgM	Target value ± 3 SD
Infectious mononucleosis	Target value ± 2 dilution or positive or negative
Rheumatoid factor	Target value ± 2 dilution or positive or negative
Rubella	Target value ± 2 dilution or positive or negative

available, a comparative method may be used. If the method group is less than 20 participants, 'target value' means the overall mean after outlier removal (as defined above) unless acceptable scientific reasons are available to indicate that such an evaluation is not appropriate."

Accepted reference methods do not exist for many of these "controlled analytes," and even when they do exist, the values obtained for PT specimens with some analytical systems may not match those obtained with the reference method owing to differences in matrices and analyte form.[91] The CAP uses peer group mean values as the targets or groups of methods that agree with the definitive method. This target value is termed the definitive method correlated target value (DMCTV). Alternatively, the all-method mean (or median) is used as the target value, but this causes problems if one manufacturer dominates the market, especially if the method used is calibrated differently than the others.

The CLIA '88 regulations specify that the PT specimens should be treated in the same manner as patient specimens and require that the personnel performing the tests sign a statement attesting that they have complied with the regulations. In reality, PT specimens must be treated differently than those from patients, since many are lyophilized or sealed in containers, and reporting of their results requires different forms and is generally not computerized. A study in England showed that "special handling" of PT specimens substantially improved the accuracy of results.[81] A survey of hospital-based laboratories in Pennsylvania showed that the majority of laboratories provided special handling for PT specimens (e.g., running tests in duplicate, reporting the average, and recalibrating methods just before analyzing PT

specimens).[20] This "special handling" does not necessarily provide better test results. In a study of proficiency testing problems at a large reference laboratory, it was found that error rates were higher if PT specimens were given special handling than if they were submitted as blind patient specimens. Moreover, it was found that most problems were caused by systematic errors and that the average of replicates did not correct these problems.[32]

A new requirement of the final CLIA regulations is that laboratories must perform method validation studies on all new tests introduced after April 24, 2003. Before this, laboratories that implemented new methods and analytical systems that had been cleared by the Food and Drug Administration (FDA) could simply follow manufacturers' directions for operation and assume that the manufacturer's performance claims were valid. With the issuance of the final rule, the performance of all new tests must be validated in each laboratory to document the reportable range, precision, accuracy, and reference intervals. For some methods, it may also be necessary to determine the detection limit and to test for possible interferences.

Another major change in the final rule was the elimination of an earlier provision that would have required the FDA to review a manufacturer's QC instructions. That was a key provision for allowing laboratories to simply follow a manufacturer's directions. However, with elimination of that provision, laboratories now have more responsibility for establishing effective QC systems that will monitor the complete analytical process, take into account the performance specifications of the method, detect immediate errors, and monitor long-term precision and accuracy.

The most controversial change in the final rule is the introduction of "equivalent QC procedures." CLIA sets a minimum level of QC that must be performed by all laboratories. Typically that requires two levels of controls to be analyzed every 24 hours, or for some tests, one level of control to be analyzed every 8 hours. The new guidelines for "equivalent QC" may allow laboratories to reduce daily QC to weekly or even monthly QC for analytical systems that have built-in procedural controls. The provision is obviously targeted for point-of-care testing (POCT) or near patient testing (NPT) where personnel lack the skills to perform QC and instead rely on instrument checks, most notably electronic checks or electronic QC. In spite of the arguments about the inadequacy of electronic QC,[104] it has become widely accepted in POCT and NPT applications. Although there is at least one example of an analytical system with improved QC technology that requires little or no external QC,[117] most analytical systems have yet to demonstrate the performance that would justify a reduction of daily QC to only weekly or monthly QC.

In the United States, as a result of the personnel standards of CLIA and current staffing shortages, many laboratories have been left without the technical and analytical skills to manage quality effectively. Consequently, in the authors' opinion, the use of statistical QC is declining in many laboratories (www.westgard.com/essay34). Thus QC has come to mean "quality compliance" rather than quality control. The consequences of a regulatory approach to quality have to be carefully assessed relative to other initiatives. Regulation does not appear to be an adequate substitute for professional responsibility for quality.

To summarize this section, PT programs are far from ideal monitors of laboratory performance. In a study of PT survey problems at the Mayo Clinic, more than one half of the errors on surveys were directly related to deficiencies in the surveys (such as invalid specimens and inappropriate evaluation criteria), and only 28% could be linked to specific analytical problems.[47] A novel PT program piloted by the New York State Department of Health involves obtaining aliquots of patient specimens that are routinely processed by the laboratory at the time of its annual inspection.[75] These specimens are reanalyzed in the state's laboratories using reference methods, and the results are compared with those obtained during inspection. This prevents problems such as the presence of unnatural specimens and the clerical errors of foreign forms. Other specimen stability problems and methodological interferences probably continue to exist.

IDENTIFYING THE SOURCES OF ANALYTICAL ERRORS

The control procedures discussed in the previous sections provide a way of alerting the analyst to problems that may cause the quality of analytical performance to fall short of the goals set for the laboratory. However, these control procedures do not identify the sources of the analytical errors and solve the control problems. The following additional procedures are often necessary to identify these sources.

Physical Inspection

When alerted to a control problem, the first step should be to carefully inspect the analytical method, equipment, reagents, and specimens. Does everything look, feel, smell, and sound correct? An inspection may seem to be a very qualitative and subjective technique, but it can be exceedingly useful when performed with checklists developed for specific analytical methods. This inspection should include a review of records documenting changes that occur with the instrument and reagents. Brief instrument function checks are often performed to verify proper system performance and to separate chemical and instrumental sources of errors. An experienced analyst can often spot the problem by making this kind of inspection, whereas inexperienced analysts will be aided by formal checklists.

Relationship of Type and Source of Error

The type of error itself provides a clue about the source of the error. For example, systematic errors are often related to calibration problems (impure calibration materials, improper preparation of calibrating solutions, erroneous set point and assigned values, unstable calibrating solutions,

contaminated solutions, inadequate calibration techniques, nonlinear or unstable calibration functions, unstable reagent blanks, and inadequate sample blanks). Random errors are more likely caused by lack of reproducibility in the pipetting of samples and reagents, to the dissolving of reagent tablets and the mixing of sample and reagents, and to the lack of stability of temperature baths, timing regulation, and photometric and other sensors. Individual analytical methods may not be subject to all of these possible sources of error; rather, there may be only a few plausible sources for a particular type of error. Experienced analysts often know what these common sources are for their particular analytical methods and quickly identify the sources once the type of error is known.

Some information about the type of error occurring is obtained by knowing which errors the control procedures respond. As discussed earlier in this chapter, different control rules have different sensitivities to detect random and systematic errors, as illustrated by the multirule control procedure. However, in practice, it is often possible to make a good judgment as to the type of error occurring based on the control procedure that provides the alert. Control procedures that employ patient samples rather than stable control materials can help identify preanalytical sources of errors, such as sample handling and processing. External quality assessment procedures that employ frozen patient samples[79] may provide more extensive information about errors than what is available from internal procedures. The information from all of these procedures is complementary and, when used in combination, provides a more complete assessment of the types of errors occurring and their possible sources.

Method Evaluation Experiments

When the type of error cannot be easily identified and quantified from available control data, it may be necessary to use the experiments employed in method evaluation studies (see Chapter 14). A "comparison-of-methods experiment" may be used to estimate systematic errors when there is another routine method available for measuring the analyte of interest. Interpretation of the results must consider that the observed differences between two methods could be caused by either method and cannot therefore be assigned to the "test" method unless the quality of the "comparison" method is well documented. Recovery, interference, and linearity experiments may be more specific in estimating systematic errors, including the constant or proportional nature of the systematic errors.

To identify sources of random error, a "replication experiment" is designed to estimate the contributions from several different components. For example, when duplicates are analyzed within a run for several different runs, the data are used to determine the components of within-run and between-run variation. This process isolates the errors occurring in different time periods, which in turn may help identify the sources of the random error. Replication experiments of this kind, using analysis of variance statistical techniques, are tailored to particular analytical systems to identify the major factors that contribute to the random error of those analytical methods. The performance of control procedures also depends on the different components of variance, and it is particularly important that the between-run component be kept as small as possible.[116]

Optimization Techniques

More complicated experimental techniques, such as factorial experiments, "simplex" optimization, and "response surface" optimization, have been used to solve complex control problems. Youden[133] described the use of a series of experiments in which several factors could be varied simultaneously, thus reducing the total number of experiments necessary to determine how these factors affect the performance of the analytical method. These "factorial" experiments have been used for testing the "ruggedness" of an analytical method (i.e., its responsiveness to any disturbance in the chosen experimental conditions). A properly optimized method should be rugged—this means that small changes in the analytical conditions should not greatly affect analytical performance. Formal optimization strategies can be employed to decide on those analytical conditions. Simplex optimization techniques have also been applied to optimize clinical chemistry methods. These techniques provide systematic approaches for selecting the analytical conditions that minimize errors and reduce control problems.

QUALITY INITIATIVES

Several organizations have developed and implemented quality initiatives to ensure that clinical laboratories and manufacturers and providers of diagnostic products incorporate the principles of quality management and assurance in their daily operations. Examples include (1) Joint Committee for Traceability in Clinical Laboratories (http://www.bipm.fr/en/committees/jc/jctlm/), (2) International Organization for Standardization (http://www.iso.ch), and (3) National Institute of Standards and Technology (http://www.nist.gov).

Joint Committee for Traceability in Laboratory Medicine (JCTLM)[30]

Many organizations have been involved in developing a traceable accuracy base for analytes of clinical interest (see Chapter 14).[30,95] A driver for current efforts to develop such a base is the European Directive 98/79/EC on in vitro diagnostic medical devices (www.ce-mark.com/ivd.pdf), which requires that: "The traceability of values assigned to calibrators and/or control materials must be assured through available reference measurement procedures and/or available reference materials of a higher order."

In 2002 the JCTLM was created to meet the requirement for a worldwide platform to promote and give guidance on

internationally recognized and accepted equivalence of measurements in laboratory medicine and traceability to appropriate measurement standards (www.bipm.org/en/committees/jc/jctlm/). The three principal participants in JCTLM are the International Bureau of Weights and Measures (BIPM), the International Federation for Clinical Chemistry and Laboratory Medicine (IFCC), and the International Laboratory Accreditation Cooperation. Other key participants include producers of certified reference materials (e.g., National Institute for Standards and Technology [NIST] and the Institute for Reference Materials and Measurements [IRMM]). In Vitro Diagnostic (IVD) manufacturers are represented by the Advanced Medical Technology Association (AdvaMed) and the European Diagnostic Manufacturers Association (EDMA); external quality assessment and proficiency testing organizations; standards organizations (e.g., the NCCLS and International Organization for Standardization (ISO)/Technical Committee 212); and regulatory bodies (e.g., FDA, European Union (EU) authorities, and the European Commission).

The JCTLM has created two working groups: (1) JCTLM WG-I, Reference Materials and Reference Procedures and (2) JCTLM WG-II, Reference Laboratory Networks. They are responsible for providing practical support to the worldwide IVD industry in establishing metrological traceability for values assigned to calibrators and/or control materials as required by the forthcoming European Directive on in vitro diagnostics and by comparable regulations in other countries.

International Organization for Standardization

The International Organization for Standardization (ISO) is a worldwide federation of national standards bodies from some 100 countries (http://www.iso.ch), one from each country that is the national body "most representative of standardization in its country." For example, the United States is represented in the ISO by the American National Standards Institute (ANSI). (The national representative for each country can be identified by accessing the ISO homepage—http://www.iso.ch.) The mission of the ISO is to promote the development of standardization and related activities in the world with a view to facilitating the international exchange of goods and services and to developing cooperation in the spheres of intellectual, scientific, technological, and economic activity. The ISO's work results in international agreements, which are published as international standards. The ISO 9000 standards are examples of such standards, and they have been applied on a worldwide basis. The ISO has also organized several technical advisory groups that address quality issues of interest to clinical laboratorians.

ISO 9000

ISO 9000 is a set of four standards for ensuring quality management and quality assurance in manufacturing and service industries. They were first published in 1987 and are used worldwide, with more than 80 countries adopting them as national standards. There have also been two large regional adoptions, the European Committee for Standardization and the Pan American Standards Commission. In brief, ISO 9000 certification is a tangible expression of an organization's commitment to quality that is recognized internationally.

The four ISO 9000 standards are:

ISO 9001	Quality systems—Model for quality assurance in design, development, production, installation, and servicing
ISO 9002	Quality systems—Model for quality assurances in production, installation, and servicing
ISO 9003	Quality systems—Model for quality assurance in final inspection and test
ISO 9004	Quality management and quality system elements—Guidelines

The ISO 9000 standards represent an international consensus on the essential features of a quality system to ensure the effective operation of any business, whether a manufacturer or service provider or other type of organization, whether in the public or private sector. Many major diagnostic companies have received ISO 9000 certification, and in 1996, the Excel Bestview Medical Laboratories of Mississauga, Ontario, Canada became the world's first clinical laboratory to receive ISO 9002 certification.[2] (Note that an organization applies for certification under the section that most closely represents its structure.) Elements of ISO 9002 certification (http://www.revereelectric.com/eleISO.html) include:

- **Management responsibility**—Requires that a quality system be defined, documented, and communicated throughout the organization, and that responsibility for quality be clearly defined. Top management must review the quality system at least once a year to ensure its continuing suitability and effectiveness.
- **Quality system**—Requires that a quality system meeting the requirements of the ISO 9002 standard be established, maintained, and documented as a means of ensuring that product conforms to requirements.
- **Contract review**—Requires review of incoming orders to ensure that requirements are clearly and completely defined, and to ensure the capability exists to meet the requirements.
- **Document control**—Requires establishing and maintaining procedures for controlling documentation through approval, issue, and modification.
- **Purchasing**—Requires purchased product to conform to specified requirements. This is accomplished through vendor assessments, clear and accurate purchasing data, and verification of purchased product where applicable.
- **Customer-supplied material**—Requires procedures for storage and maintenance of customer-supplied product.

Product identification and traceability—Requires procedures for identifying and tracing product if required by the customer.

Process control—Requires procedures to ensure that production processes are carried out under controlled conditions. This includes the documentation, monitoring, and control of suitable process characteristics; use of approved equipment; and workmanship standards.

Inspection and testing—Requires procedures for inspection and testing at receiving, in process, and before shipment.

Inspection, measuring, and test equipment—Requires procedures for selection, control, calibration, and maintenance of measuring and test equipment.

Inspection and test status—Requires evidence to indicate conformance or nonconformance to inspections and tests performed.

Control of nonconforming product—Requires procedures to ensure that product that does not conform to requirements is prevented from unintended use or installation. This includes identification, documentation, evaluation, segregation, and disposition of nonconforming product.

Corrective and preventive action—Requires procedures for the investigation of the cause of nonconformities, actions to eliminate them, and controls to prevent them from recurring.

Handling, storage, packaging, preservation, and delivery—Requires procedures for handling, storing, packaging, preserving, and delivering products to prevent damage or deterioration.

Control of quality records—Requires procedures for identification, collection, indexing, access, filing, storage, maintenance, and disposition of quality records.

Internal quality audits—Requires internal audits by personnel independent of the audited activity to verify whether quality activities comply with requirements and to determine the effectiveness of the quality system.

Training—Requires procedures for identifying training needs and providing training for all personnel to meet them.

Servicing—Requires procedures for performing, verifying, and reporting that the servicing meets specified requirements.

Statistical techniques—Requires procedures, when appropriate, for identifying the necessity for statistical techniques required for establishing, controlling, and verifying process capability.

ISO certification is carried out by accredited organizations known as registrars. Registrars review the organization's quality manual and audit the process to ensure that the system documented in the manual is in place and effective. When an organization receives ISO 9000 certification, benefits are recognized both internally and externally. Internally, it becomes a tool with which to monitor the quality system and to document continuous improvements. In addition, having a documented system ensures consistency, productivity, and effectiveness in all the daily functions of business. Externally, existing and potential customers have confidence knowing that the products or services that they purchase were processed under a controlled and documented system.

ISO Technical Advisory Groups for Laboratory Standards

The ISO also has a number of other activities that relate to quality activities in the clinical laboratory. For example, in response to an NCCLS proposal, the ISO organized in 1995 a Technical Advisory Group (TC 212-Clinical Laboratory Testing and In Vitro Diagnostic Testing Systems). The ISO has delegated responsibility for managing TC 212 to the United States (i.e., ANSI). ANSI in turn has delegated this responsibility to NCCLS. Creation of this technical committee provides a focus for coordination of international standardization in the field of laboratory medicine and in vitro diagnostic test systems. This includes, for example, quality management, preanalytical and postanalytical procedures, analytical performance, laboratory safety, reference systems, and quality assurance. Four working groups for TC 212 have been organized: (1) WG 1—Quality management in the clinical laboratory, (2) WG 2—Reference systems, (3) WG 3—In vitro diagnostic products, and (4) Antimicrobial susceptibility testing. These working groups have produced a number of documents (Table 19-9).

ISO 15189:2003 is an example of an ISO document; it was published by the ISO in 2003 and is based on ISO 9001:2000 and ISO 17025:1999, the latter being a standard for testing and calibration laboratories.

It identifies specific management requirements, such as laboratory organization and management, a quality management system, document control, review of contracts, evaluation by referral laboratories, external services and supplies, advisory services, resolution of complaints, identification and control of nonconformities, corrective action, preventive action, continual improvement, quality and technical records, internal audit, and management review. Technical requirements cover personnel, accommodation and environmental conditions, laboratory equipment, preexamination procedures, examination procedures, assuring quality of examination procedures, postexamination procedures, and reporting of results. Annexes provide tables that correlate the requirements between ISO 9001:2000 and ISO/IEC 17025:1999. In addition, there are annexes with recommendations for protection of laboratory information systems, ethics in laboratory medicine, and POCT.

Other ISO technical committees that relate to quality in healthcare include (1) TC 48—Laboratory Glassware and Related Apparatus; (2) TC 76—Transfusion, Infusion, and Injection Equipment for Medical Use; (3) TC 176—Quality Management and Quality Assurance; and (4) TC 210—

TABLE 19-9 ISO Standards Relevant to Clinical Laboratories

Number	Title
ISO 15189:2003	Medical laboratories—particular requirements for quality and competence
ISO 15190:2003	Medical laboratories—requirements for safety
ISO 15193:2002	In vitro diagnostic medical devices—measurement of quantities in samples of biological origin—presentation of reference measurement procedures
ISO 15194:2002	In vitro diagnostic medical devices—measurement of quantities in samples of biological origin—description of reference materials
ISO 15195:2003	Laboratory medicine—requirements for reference measurement laboratories
ISO 15197:2003	In vitro diagnostic test systems—Requirements for blood glucose monitoring systems for self-testing in managing diabetes mellitus
ISO 17511:2003	In vitro diagnostic medical devices—measurement of quantities in biological samples—metrological traceability of values assigned to calibrators and control materials
ISO 18153:2003	In vitro diagnostic medical devices—measurement of quantities in biological samples—metrological traceability of values for catalytic concentration of enzymes assigned calibrators and control materials
ISO 19001:2002	In vitro diagnostic medical devices—information supplied by the manufacturer with in vitro diagnostic reagents for staining in biology
Draft Documents	
ISO/DIS 15198	Clinical laboratory medicine—in vitro diagnostic medical devices—validation of manufacturer's recommendations for user quality control
ISO/CD 22869	Technical Report: Medical laboratories—guidance on laboratory implementation of ISO 15189
ISO/CD 22870	Amendment to 15189: Annex D—point-of-care testing (POCT)

Quality Management and Corresponding General Aspects for Medical Devices. The NCCLS also administers the U.S. Technical Advisory Group for ISO/TC 76 on Transfusion, Infusion, and Injection Equipment for Medical Use. ISO/TC 76 is particularly concerned with development of standards for glass containers for blood transfusions, plastic containers for blood collection and transfusion, and blood specimen containers for hematology and biochemistry.

Preparing for ISO Accreditation

In 2002 Burnett compared ISO standards and synthesized an "ideal standard" that becomes a practical guide for laboratories preparing for ISO accreditation.[11] In his comparison, he supplements the original ISO standards and illustrates their application using a fictitious pathology laboratory and hospital (St. Elsewhere's Hospital Trust). In that context, there are many examples of specific forms and policies that would be appropriate for a laboratory. He also provides additional technical information about the quality required for the "intended use" of laboratory tests, which is important if the goal of uniform quality is to be achieved for a patient who moves from place to place and country to country.

Malcolm Baldridge National Quality Award

The Malcolm Baldridge National Quality Award was established by Congress in 1987 to enhance U.S. competitiveness by promoting quality awareness, recognizing quality achievements of U.S. companies, and publicizing successful performance strategies. In conjunction with private industry, the Commerce Department's National Institute of Standards and Technology (http://www.nist.gov) manages the award program. The award is not given for specific products or services. Currently, two awards may be given annually in each of three categories: manufacturing, service, and small business.

Seven areas are evaluated when a company applies for the award: (1) leadership, (2) information and analysis, (3) strategic planning, (4) human resource development and management, (5) process management, (6) business results, and (7) customer focus and satisfaction. Applicants must address a set of examination items within each of these categories. Heavy emphasis is placed on business excellence and quality achievement as demonstrated through quantitative data furnished by applicants. A useful consequence of the award has been the development of worksheets that an organization uses to measure and score its performance against the seven Baldridge criteria.[31] By assessing its quality program against these criteria, an organization verifies the status of its program and identify areas where improvements have to be made.

CHAPTER 20

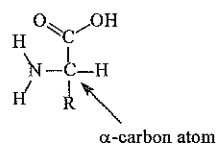
Amino Acids, Peptides, and Proteins*

A. Myron Johnson, M.D.

Amino acids, peptides, and proteins play crucial roles in virtually all biological processes, with amino acids being the basic structural units of proteins. Many genetic mutations result in the incorporation into proteins of amino acids that may alter rates of synthesis, secretion, or metabolism of the proteins and their function. In addition, there are a large number of inherited abnormalities of amino acid metabolism (see Chapter 55).

It is estimated that there are more than 50,000 human proteins, and that the number of distinct proteins within one cell is 3000 to 5000. More than 1400 different proteins can be identified in serum alone. Some proteins are elaborated or circulate only at certain stages of growth or under particular physiological or pathological circumstances. Many proteins are structural elements of cells or organized tissue and can be evaluated only after their separation from the tissue where they reside; others are soluble in intracellular or extracellular fluids. Some soluble proteins that are normally intracellular escape into extracellular and intravascular fluids when cells are damaged; some may be shed into blood or urine in detectable quantities. The variety of proteins is much greater than expected from the number of coding genes because of postsynthetic modifications that may make them selectively functional or degradable. Not only is the number of distinct proteins very large, but also their variations of concentration in health and disease, their distribution in the body, their functions, their compositions, and their structures are seemingly infinite.

*The author gratefully acknowledges the previous contributions of Robert H. Christenson, Hassan M.E. Azzazy, Lawrence M. Silverman, and Elizabeth M. Rohlfs, on which portions of this chapter are based.

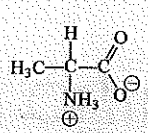


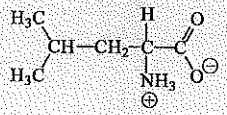
This chapter begins with a discussion of amino acids, followed by specific discussions of proteins in plasma and in other fluids and miscellaneous proteins. It concludes with descriptions of analytical techniques used to analyze proteins.

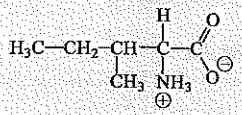
AMINO ACIDS

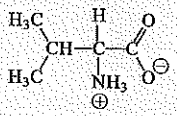
Amino acids are the basic structural units of proteins. Their measurement in physiological fluids provides important information for fundamental studies and the diagnosis of many pathological and inherited conditions.

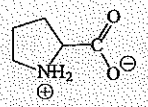
Basic Biochemistry

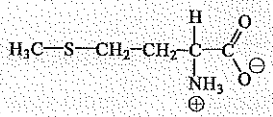


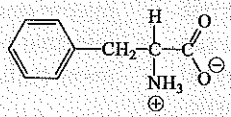


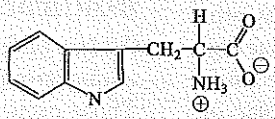


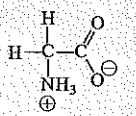


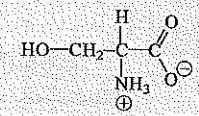


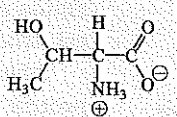






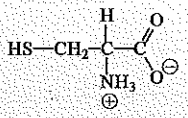


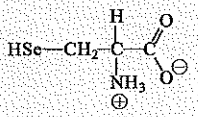


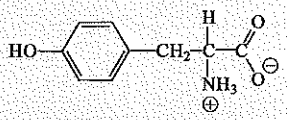


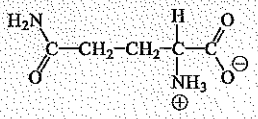
Amino acids are organic compounds containing both an amino group ($—NH_2$) and a carboxyl group (—COOH). Those occurring in proteins are called α-amino acids and have the empirical formula $RCH(NH_2)COOH$. As shown below, the core of an α-amino acid is the carbon atom next to the carboxylic acid group.

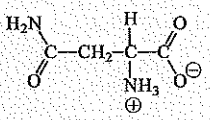
With the exception of glycine, all amino acids are asymmetrical, having a hydrogen atom, a carboxyl group, an amino group, and a distinctive R group of a specific chemical structure.

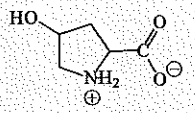


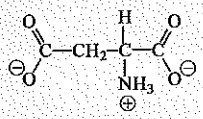


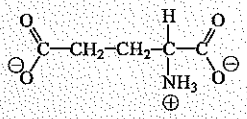


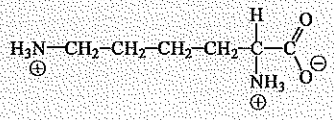












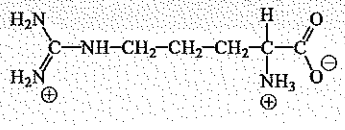


Table 20-1 lists the amino acids that are of importance in protein chemistry. The variety of amino acids provides a large portion of the variability in structure and function of

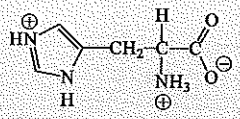
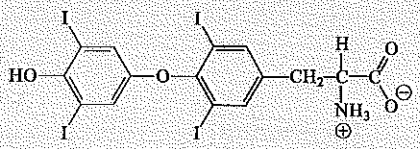
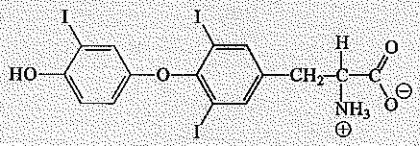
TABLE 20-1 Amino Acids

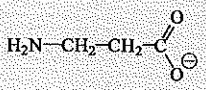
Name and Abbreviation	MW	Structure at pH 6–7	Comments
I. Amino Acids Found in Most Proteins			
Hydrophobic Amino Acids; Nonpolar R Groups			
Alanine Ala	89.09		Substrate for ALT; least hydrophobic of the group
Leucine Leu	131.17		Branched-chain R group; essential; ketogenic; metabolism is faulty in maple syrup urine disease
Isoleucine Ile	131.17		Essential; partly ketogenic; see Leucine above
Valine Val	117.17		Essential; partly ketogenic; see Leucine above
Proline Pro	115.13		Important constituent of connective tissue proteins (e.g., collagen and elastin); some hydroxylated to Hyp during collagen synthesis; destabilizes α-helical and β-structures; contains an α-imino group
Methionine Met	149.21		Essential; important in transfer of methyl groups; provides sulfur for other sulfur-containing compounds
Phenylalanine Phe	165.19		Essential; elevated levels in phenylketonuria
Tryptophan Trp	204.22		Essential; metabolites found in carcinoid disease; contains indole ring system; precursor of serotonin and melatonin
Hydrophilic Amino Acids; Uncharged Polar Groups			
Glycine Gly	75.07		Simplest amino acid; optically inactive; placed in this group because its R group (single H) is unable to affect polarity of the rest of the molecule; used in biosynthesis of purines and porphyrins; used in vitro as a buffer
Serine Ser	105.09		Constituent in active center of many enzymes; hydroxyl group can be phosphorylated
Threonine Thr	119.12		Essential

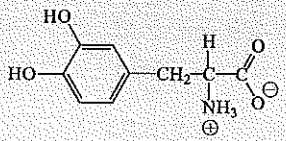
ALT, Alanine transaminase.

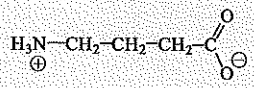


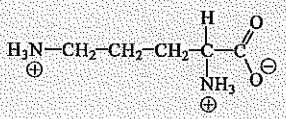


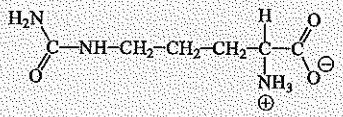


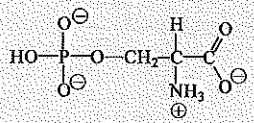


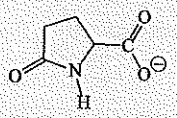


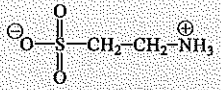












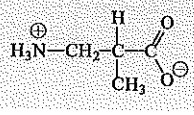


TABLE 20-1 Amino Acids—*Continued*

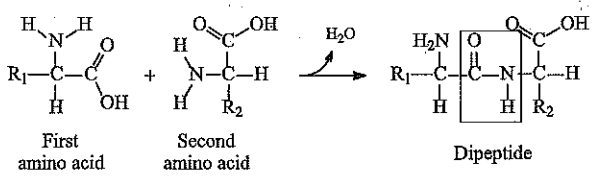
Name and Abbreviation	MW	Structure at pH 6–7	Comments
I. Amino Acids Found in Most Proteins—Cont'd			
Hydrophilic Amino Acids; Uncharged Polar Groups—Cont'd			
Cysteine Cys	121.16		Sulfhydryl group functional in the activity of many enzymes; is responsible for disulfide bridges in peptides and proteins; cystine is dicysteine, Cys-S-S-Cys; homocysteine has one carbon more than cysteine and forms homocystine (dihomocysteine)
Selenocysteine Secys	168.05		Active form of selenium; found in many enzymes involved in oxidation-reduction reactions
Tyrosine Tyr	181.19		Usually nonessential; intermediate in synthesis of catecholamines, thyroxine, and melanin; functional phenolic group; reacts with Folin's reagent in quantitative protein assay
Glutamine Gln	146.15		Storage form of ammonia in tissue; supplies the amido nitrogen used in purine and pyrimidine biosynthesis
Asparagine Asn	132.12		Storage form of ammonia in tissues
Hydroxyproline Hyp	131.13		Constituent of collagen—the only human protein to contain appreciable amounts; urinary output is used as an indicator of bone matrix metabolism; contains an α-imino group
Dicarboxylic Amino Acids; Acidic R Groups			
Aspartic acid Asp	133.10		Cosubstrate with Glu for AST; used in pyrimidine biosynthesis
Glutamic acid Glu	147.13		Co-substrate with Ala for ALT and with Asp for AST
Basic Amino Acids; Basic R Groups			
Lysine Lys	146.19		Essential; terminal NH_2 called ε-amino
Arginine Arg	174.20		Involved in urea synthesis; the basic group is a guanidinium group

AST, Aspartate transaminase.

Continued.

TABLE 20-1 Amino Acids—*Continued*

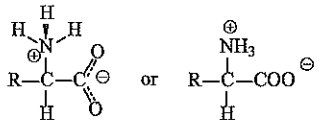


Name and Abbreviation	MW	Structure at pH 6–7	Comments
I. Amino Acids Found in Most Proteins—Cont'd *Basic Amino Acids; Basic R Groups—Cont'd*			
Histidine His	155.16		The imidazole group of histidine is the most important buffer group in the physiological pH range
II. Miscellaneous Amino Acids			
Thyroxine T_4	776.93		Thyroid hormone
Triiodothyronine T_3	651.01		Thyroid hormone; more active than T_4
β-Alanine β-Ala	89.09		Constituent of the vitamin pantothenic acid
Dihydroxyphenylalanine DOPA*	197.18		Intermediate in catecholamine synthesis
γ-Aminobutyric acid GABA*	103.12		Metabolite of Glu; a neurotransmitter
Ornithine Orn*	132.16		Intermediate in urea synthesis
Citrulline Citr*	175.19		Intermediate in urea synthesis
Phosphoserine	185.08		In casein and other phosphoproteins
Pyrrolidine carboxylic acid	129.12		Cyclized form of Glu, rare; used to terminate peptide chains, as at *N*-terminal end of L-chains of γ-globulins
Taurine	125.14		Forms conjugates with bile acids; inhibits nerve impulse transmission
β-Aminoisobutyric β-AIB*	103.12		Present in urine; a metabolite of pyrimidines

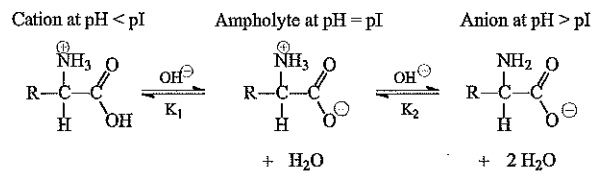
*Abbreviation useful but not official.

peptides and proteins, in which amino acids are combined via *peptide bonds* formed between the α-amino group of one and the α-carboxyl group of the next.

Peptide Bond



A *peptide bond* is formed when the amino group of one amino acid is covalently linked with the carboxyl group of a second amino acid.



The peptide bond is described by the structure in the enclosed area. For example, glycine and alanine react to form two different dipeptides, either glycylalanine or alanylglycine.

Acid-Base Properties

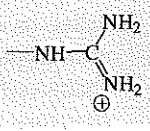
Acid-base properties of amino acids depend on the amino and carboxyl groups attached to the α-carbon and on the basic, acidic, or other functional groups represented by R. In the illustration above, the amino acid is shown in an uncharged form. However, in the physiological pH range of 7.37 to 7.47, the carboxyl group is dissociated, and the amino group is protonated to give the following structure:

This kind of ionized molecule, having coexistent negative and positive charges, is called a *dipolar ion* or *ampholyte*. At low pH, both the amino and carboxyl groups are protonated as $—N^+H_3$ and —COOH, and the amino acid is cationic. As the pH rises, the carboxyl group loses its proton and the ampholyte form appears at about pH 6. At higher pH, the amino $—N^+H_3$ is also deprotonated, and the molecule is anionic. The process is shown for a monoamino acid and monocarboxylic amino acid as follows:

The dissociation constants, K_1 (ratio of ampholyte to cation) and K_2 (ratio of ampholyte to anion), are usually expressed logarithmically as pK_1 and pK_2, where $pK = -\log K$, in a manner analogous to the notation for pH. A pK is the pH at which equal quantities of the protonated (associated) and unprotonated (dissociated) forms are present. The *isoelectric point*, pI, is the pH where the molecules exist in the ampholyte form and have a net charge of 0. The pI of a neutral amino acid can be calculated from the p*K*s of its amino and carboxyl groups ($pI = \frac{1}{2}[pK_1 + pK_2]$). The concept of an ampholyte and its dissociation characteristics is also applicable to proteins as most are negatively charged at physiological pH.

Glycine, with a pK_1 of 2.34 and pK_2 of 9.60, exemplifies the acid-base behavior of amino acids whose R groups have no ionizable constituents. Glycine is sometimes used in vitro to prepare buffers at pH 1.0 to 3.8 or 8.1 to 11.0. The ionization constants in amino acids are given in Table 20-2.

Influence of R Groups



The R groups of individual amino acids are responsible for many of their special properties. Table 20-1 is organized in terms of the differences in R groups, some of which are nonpolar and therefore hydrophobic; others, although uncharged, are polar and hydrophilic. Still others become charged either negatively (the acidic amino acids) or positively (the basic amino acids). R groups may be linear as in valine or cyclical as in proline, small as in glycine or bulky as in tryptophan. Electron density may be low as in aliphatic chains or high as in aromatic rings. This diversity in R group structure and chemistry makes possible several kinds of interaction between the amino acids that are of great importance in determining protein structure and function. Possible interactions among R groups include disulfide bonds, hydrogen bonds, hydrophobic interaction, and steric effects. The disulfide bond (—S—S—) is the only covalent bond, other than the peptide bond, that contributes to polypeptide structure.

The other types of interactions are weaker but are often so numerous that their collective strength is large. Hydrogen bonds result from the sharing of a hydrogen atom between two electronegative atoms (e.g., N or O) that have unbonded electrons. In proteins, groups having a hydrogen atom that can be shared include ═N—H (peptide nitrogen, imidazole, and indole); —OH (serine, threonine, tyrosine, and hydroxyproline); $—NH_2$ and $—N^+H_3$ (arginine, lysine, and α-amino); and —CONH (carbamino). Groups that can accept the sharing of a hydrogen atom include $—COO^-$ (aspartate, glutamate, and α-carboxylate); —S—S— (disulfide); and ═CO (in peptides and ester linkages). Examples of hydrogen bonds linking the ═CO of one peptide bond to the ═NH of another, or the —CO— of one R group to the —OH of another R group.

Hydrophobic interactions result because the association of nonpolar groups (e.g., methyl or phenyl) is energetically favored in aqueous or other polar solutions. In proteins, this association serves to bend and fold a molecule in a way that brings nonpolar R groups inside to the less polar interior; polar R groups are oriented outside toward the more polar aqueous environment.

Some amino acids have R groups that contain charged or ionizable constituents. These constituents have their own

TABLE 20-2 Ionization Constants of Ionizable Groups in Free Amino Acids and in Proteins*

Ionizing Group		Range of pK Values: Free Amino Acids	Range of pK Values: Proteins
Principal carboxyl = pK_1		1.7-2.6	3.0-3.2
α-Amino = pK_2		9.0-10.8	7.6-8.4
Second carboxyls of Glu and Asp		3.8-4.3	3.0-4.5
Imidazole nitrogen of His		6.0	0.6-7.0
Sulfhydryl of Cys		8.3	9.1-10.8
Phenolic hydroxyl of Tyr		10.1	9.2-9.8
ε-Amino of Lys		10.5	9.4-10.6
Guanidinium group of Arg		12.5	11.5-12.6

*Given are the p*K* values for proton-donating charged groups when present in free amino acids and when present in peptide-linked amino acid residues in proteins. The p*K* value for the primary carboxyl varies from 1.71 for Cys to 2.63 for Thr. Similarly, the p*K* for the α-ammonium group varies from 8.95 for Lys to 10.78 for Cys. In protein chains, the proximity of other amino acid residues and charged groups may modify the p*K* for any given ionizable group. The amino acid symbols are those listed in Table 20-1.

p*K*s, which are also shown in Table 20-2. At pH 7, the acidic amino acids, glutamic acid (Glu) and aspartic acid (Asp), have their second carboxyl group fully ionized and are therefore negatively charged in the physiological pH range. Except for histidine, most basic amino acids are positively charged at physiological pH (less than 10% of histidine is positively charged in this range). Charges that reside or develop on R groups are responsible for electrostatic bonding, which may occur in proteins or between a protein and a ligand.

The differing solubilities and acid-base properties of amino acids provide the basis for their separation by electrophoresis, partition chromatography, or ion-exchange chromatography (see Chapters 5 and 6). Differences in the chemical nature of R groups permit, in some cases, their identification or measurement by color reactions. The aromatic amino acids—tyrosine and tryptophan—absorb ultraviolet (UV) light at 280 nm; all amino acids absorb UV radiation at 220 nm. The absorption at 280 nm can be used to estimate the concentration of an individual protein in solution, such as fibrinogen. Aside from the distinctive properties used for analyses, the general and special properties of amino acids are critical to the role they have in determining the structure and function of proteins.

Metabolism

In the healthy state, the primary supply of amino acids for endogenous protein synthesis is provided by dietary proteins. Although most of the amino acids can be formed in vivo, 8 to 10 of the 22 common amino acids cannot be synthesized by most mammals and are therefore considered "essential" constituents of the diet for maintenance of health or growth, or both (see Table 20-1, Comments column). Proteolytic enzymes in the gastrointestinal tract act on ingested proteins, releasing amino acids that are then absorbed from the jejunum into the blood and subsequently become part of the body pool of amino acids. The liver and other tissues draw on this pool for synthesis of plasma and intracellular proteins. The liver and kidneys are also actively involved in interconverting amino acids by transamination and degrading them by deamination. Deamination produces ammonium ions, which are rapidly consumed in the synthesis of urea. Urea in turn is excreted by the kidneys. The major pathways of amino acid metabolism are outlined in Figure 20-1.

Amino acids in blood are filtered through the glomerular membranes but are normally reabsorbed in the renal tubules by saturable transport systems (see Chapter 45). Hence, high blood levels of amino acids may result in significant renal excretion *(aminoaciduria)*. In normal individuals, aminoaciduria is transient and is associated with protein intake in excess of amino acid requirements for repletion of the body pool. The mechanism of reabsorption is not fully understood, although it is known to be an active transport system dependent on membrane-bound carriers and intraluminal Na^+ concentration. Four different transport systems

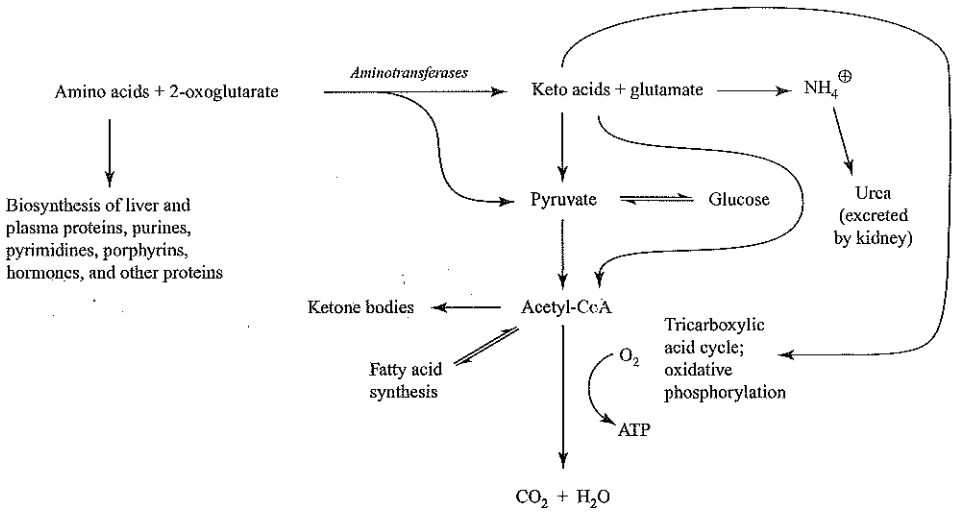


Figure 20-1 A generalized scheme of amino acid metabolism in the liver.

have been identified: one for neutral amino acids; one for basic amino acids; one for proline, hydroxyproline, and glycine; and one for dicarboxylic amino acids. For some amino acids, transport appears to occur by two systems: one of low capacity but of high specificity and the other of high capacity but of low specificity. A few amino acids, such as cystathionine and homocysteine, are not efficiently reabsorbed by renal tubular mechanisms but are cleared by the kidneys and apparently excreted into the urine at the glomerular filtration rate.

Much that is known about renal reabsorption mechanisms has been learned from the study of various forms of aminoaciduria. Three types of aminoaciduria have been identified: (1) *overflow aminoaciduria* occurs when the plasma level of one or more amino acids exceeds the renal threshold (tubular capacity for reabsorption); (2) *renal aminoaciduria* occurs when plasma levels are normal but the renal transport system has a congenital or acquired defect; and (3) *no-threshold aminoaciduria* occurs when excessive amounts of an amino acid, arising from an inherited metabolic block, are present in urine, but plasma levels are essentially normal because all the amino acid is excreted. The no-threshold aminoacidurias, such as homocystinuria, are not due to congenital or acquired kidney defects but solely to saturation of the normal renal tubular reabsorption mechanisms.

Plasma amino acid concentrations are high during the first days of life, especially in premature neonates, but they tend to be low in infants with birth weights low for their gestational age because of placental insufficiency. Maternal values are low in the first half of pregnancy. In adults, increased plasma levels of homocysteine have been linked to increased risk of heart disease (see Chapters 26 and 44).[73]

Plasma amino acid concentrations vary by about 30% during the day; therefore blood specimens should be collected at the same time each day. Values are highest in mid-afternoon and lowest in early morning. This diurnal variation is particularly important when specimens are analyzed for detection of heterozygous states of defective metabolism.

Amino acid excretion in urine varies with maturation of renal tubular function. Premature infants, especially during the first week, have a generalized physiological renal aminoaciduria (see Figure 20-2); even at full term, aminoaciduria is more pronounced than in normal adults. In the urine of normal adults, glycine is usually the dominant fraction, with alanine, serine, glutamine, and—in indulgent meat eaters—histidine and 1-methylhistidine present in smaller quantities. In some normal urine, taurine is prominent; in others, β-aminoisobutyric acid is seen.

Cerebrospinal fluid (CSF) concentrations of most amino acids are lower than those in plasma even though the rate of amino acid transport into the central nervous system is high. The plasma to CSF concentration ratios for individual amino acids vary because of differences in transport systems.

Cells have free amino acid concentrations about 10 times those of plasma. The mechanisms maintaining this tenfold β-aminoisobutyric acid is seen. The mechanisms maintaining the gradient are unknown but may involve the membrane enzyme γ-glutamyl transferase.

Clinical Implications

Aminoacidurias may be primary or secondary. Primary disease is due to an inherited enzyme defect, also called an *inborn error of metabolism.* The defect is located either in the pathway by which a specific amino acid is metabolized or in the specific renal tubular transport system by which the amino acid is reabsorbed. Secondary aminoaciduria is due to disease of an organ, such as the liver, which is an active site of amino acid metabolism, or to generalized renal tubular dysfunction, or to protein-energy malnutrition. Specific inborn errors of metabolism are discussed in more detail in Chapter 55.

Analysis of Amino Acids

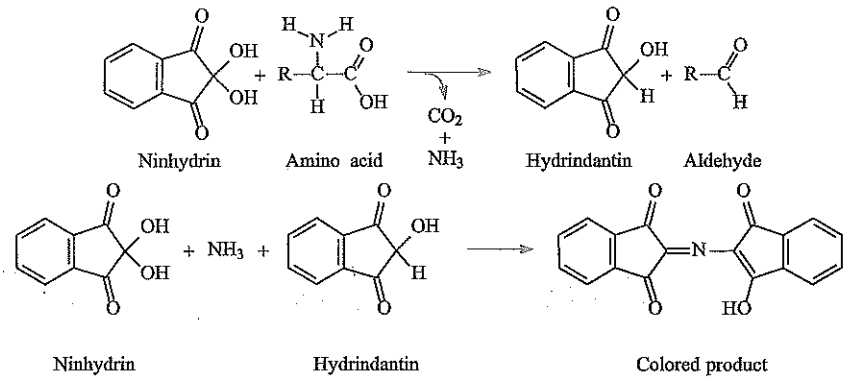
Many procedures are available for measuring amino acids in biological samples.[114] In the context of diagnosing pathological disorders, three groups of tests for amino acid analysis are of importance:

1. Screening tests, including thin layer chromatography (TLC), urine color tests, and the Guthrie microbiological test. (Details of these tests are given in a previous edition of this textbook.)[22]
2. Quantitative tests for monitoring treatment or confirming an initial diagnosis. High-performance liquid chromatography (HPLC) and ion-exchange chromatography are widely used for this purpose. Some individual amino acids may also be determined by quantitative chemical methods.
3. Tests that identify an unknown amino acid or metabolite.

Quantitative Tests

Traditionally, amino acids have been quantitatively measured in body fluids using gas chromatography (GC)[129]; liquid chromatography (LC), including HPLC[105] and ion-exchange liquid chromatography[44,65]; and capillary electrophoresis (CE).[50] These techniques are being replaced by tandem mass spectrometry (MS/MS).[17]

Gas Chromatography



Advantages of GC include small sample size, sensitivity, and speed, but a major limitation is the relatively low volatility of amino acids at temperatures conventionally used in this technique (see Chapter 6).[129] However, these compounds can be reacted with derivatizing agents to increase volatility and to enhance their chromatographic and detection characteristics.

Because of the necessity for an initial cleanup step followed by derivatization, GC is not used routinely in the clinical laboratory. However, it is still used for investigation of organic acidurias.

Liquid Chromatography

Because of its excellent sensitivity, high resolution, and relatively short analysis time, ion-exchange liquid chromatography and HPLC have been used to measure amino acids in biological samples (see Chapter 6).[44,65,105] The major advantage of these liquid chromatographic techniques over GC is that the relatively high temperatures necessary for sample volatilization by GC are unnecessary and they avoid the problem of amino acid decomposition at high temperatures.

Only a few amino acids are detected by the UV or visible spectrophotometers, fluorometers, or electrochemical detectors that are routinely used with HPLC analyzers. Consequently, amino acids typically are postcolumn derivatized for analysis by HPLC. The most widely used reagent for this purpose is ninhydrin. A number of colored products are formed, but the major one is presumed to result from deamination and condensation as follows:

Most amino acids react with ninhydrin at ambient temperatures to form a blue color that becomes purple on heating. However, proline and hydroxyproline yield yellow compounds that are measured at a different wavelength. Other postcolumn derivatizations use fluorogenic reagents, such as *o*-phthaldialdehyde or fluorescamine. Precolumn derivatization techniques using *o*-phthaldialdehyde, dansyl, phenyl isothiocyanate, or 9-fluorenylmethyl chloroformate derivatives have been used with reversed-phase HPLC. Electrochemical detection has also been coupled with derivatization methods to enhance analytical sensitivity.

Capillary Electrophoresis

In CE, the classic techniques of electrophoresis are performed in small-bore (10 to 100 μm) fused silica capillary tubes of 20 to 200 cm in length (see Chapter 5). It is a very efficient, rapid, sensitive, and versatile analytical technique that is used to analyze a diverse spectrum of analytes ranging from small ions to macromolecular proteins or nucleic acids.[50,62] When coupled with sensitive detectors, it is capable of measuring femtomolar quantities of amino acids.

Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) is applicable to the rapid assay of specific analytes in complex biological fluids (see Chapter 7).[13] In practice, it is usually interfaced to a GC[88] or LC.[12] MS/MS has been used to screen neonates[18,19,35,102] for such amino acid metabolic disorders as phenylketonuria (PKU),[20] maple syrup urine disease (MSUD),[16] tyrosinemia,[20] hypermethioninemias,[17] and homocystinuria.[17]

Compared with older methods, MS/MS is a more sensitive technique, offers greater accuracy and precision,[15] has higher clinical specificity and sensitivity, and measures multiple analytes. It has been described as a revolutionary technique for disease detection.[14,82]

PEPTIDES AND PROTEINS

This section begins with a general discussion of the basic biochemistry of peptides and proteins followed by discussions of different proteins. It concludes with a section on the analysis of proteins.

Basic Biochemistry

As discussed earlier, a peptide bond is formed when the α-amino group of one amino acid is linked covalently with the α-carboxyl group of a second amino acid. For example, glycine and alanine can react to form two different dipeptides: either glycylalanine or alanylglycine.

In glycylalanine, alanine is called the *C*-terminal residue of the peptide; glycine is the *N*-terminal residue because its amino group is free. In alanylglycine, the designations are reversed. The *C*- and *N*-terminal designations apply also to polypeptides and proteins. Very short peptide chains are designated as tripeptides, tetrapeptides, or pentapeptides, and so on. Glutathione, for instance, is a tripeptide of glutamine (Glu), cysteine (Cys), and glycine (Gly). The hormones oxytocin and vasopressin are nonapeptides. Chains up to five residues are called *oligopeptides,* and longer chains (6 to 30 residues) are referred to as *polypeptides.* When the number of amino acids exceeds 40 (MW ~ 5000 Da), the chain takes on the physical properties associated with proteins.

The terms *proteose* and *peptone* refer to protein breakdown products of large polypeptides; these differ from true proteins in that they are not coagulated by heat. A wide variety of peptides are formed when proteins are hydrolyzed in the digestive tract or in the laboratory.

The structure of a protein is described at four levels:

1. *Primary structure* refers to the identity and specific order of amino acid residues in the polypeptide chain. This sequence, which depends exclusively on covalent (peptide) bonds, is predetermined by the DNA coding (see Chapter 36); the three-dimensional structure and any special biological properties of the protein follow automatically from this amino acid sequence that folds itself into the most stable structure possible under physiological conditions.
2. *Secondary structure* may be defined as a regular recurring arrangement in space of the primary structure extending along one dimension. The secondary structures of many globular proteins have stretches of α-helix and random coils, all dependent on numerous hydrogen bonds and occasional disulfide covalent bonds.

3. *Tertiary structure* involves the intramolecular folding of the polypeptide chain into a compact three-dimensional structure with a specific shape. This structure is maintained by electrovalent linkages, hydrogen bonds, disulfide bridges, van der Waals forces, and hydrophobic interactions. Hydrophobic interactions are considered to be a major force in maintaining the unique tertiary structure of proteins.
4. *Quaternary structure* refers to the association of several polypeptide chains or subunits into a larger "oligomeric" aggregate unit. This structure depends on the close fit of the polypeptide subunits through interactions at their contact surfaces and with any prosthetic groups.

X-ray diffraction was the primary method used to investigate protein structure in early years. However, other physical, chemical, and biological methods are now used and a number of databases of protein structure have been developed. It is expected that genomics and proteomics (see Chapters 7 and 36) will greatly expand the number of sequenced proteins.

Some proteins contain non–amino acid components known as *prosthetic groups.* Such proteins are often referred to as *conjugated proteins* and are classified according to the nature of their prosthetic groups as metalloproteins, glycoproteins or mucoproteins, phosphoproteins, and so on. Both glycoproteins and mucoproteins have covalently linked carbohydrate prosthetic groups, but the amount of carbohydrate varies—up to 15% in glycoproteins and 15% to 75% in mucoproteins. Many proteins also contain and/or transport ligands, including lipids, hormones, metal ions, and so forth. Conjugated proteins freed of their ligands are called *apoproteins* (e.g., lipoproteins without lipid are called apolipoproteins, and ceruloplasmin without copper is called *apoceruloplasmin*).

Although the soluble globular proteins are especially important in clinical chemistry, thorough investigation of the insoluble, protease-resistant fibrous proteins has revealed many of the basic principles of the three-dimensional structures of proteins. The most familiar fibrous proteins are the α-keratins, which form the principal structural proteins of epidermis, hair, and nails. A molecule of α-keratin is composed of three right-handed α-helix coils supercoiled around each other. Each coil is held together by hydrogen bonding between peptide CO and NH groups of one coil and those of the next or previous coil. The amino acids of these coils include many cysteine residues, which bind the separate α-helices to one another by disulfide bonds aided by hydrogen and electrovalent bonds. This structure gives α-keratins their high tensile strength, flexibility, and elasticity.

Silk contains another type of fibrous protein structure, called a *β-sheet conformation* because of the rippled or pleated structure of these molecules. The polypeptide chains of the extended coils are bound together laterally by disulfide covalent bonds and hydrogen bonds, which connect the peptide bonds of different chains instead of connecting different coils of the same chain as in an α-helix. The β-sheet is strong and inflexible when force is applied parallel to the covalently bonded or long axis, whereas an α-helical structure—such as hair—elongates when tension is applied from an α-helix to a β-sheet structure.

Nearly all proteins of interest in clinical chemistry are soluble globular proteins, such as hemoglobin, enzymes, and most plasma proteins (with the notable exception of fibrinogen). The complex bending and folding of their polypeptide chains are a result of the numerous interactions of their R groups. Globular proteins are compact and have little or no space for water in the interior of the molecule, where most of the hydrophobic R groups are located. On the other hand, most polar R groups are located on the surface of the protein, where they exert a substantial influence on protein solubility, acid-base behavior, and function.

Most globular proteins are fragile, retaining their biological activity within only very limited ranges of temperature and pH, at which their native structural conformations are the most stable. Even short periods of exposure to temperatures of 65 °C to 70 °C or to extremes of pH cause the molecules of protein to "denature," with a concomitant loss of solubility and biological activity. During denaturation, the polypeptide chains of the protein molecules become unfolded or their quaternary structure is lost; their amino acid sequence, however, remains unchanged. After mild denaturation by a change in pH or by the action of agents such as urea, many protein molecules are able to revert spontaneously to their most stable or native globular forms and regain their biological functions when physiological conditions are restored. This is convincing evidence that the amino acid sequence alone determines their normal complex shapes. If, however, a high activation energy barrier exists between the two states, the denatured state does not revert to the native state. Many enzymes, for example, lose their catalytic function irreversibly after denaturation occurs (see Chapter 8).

Many of the properties of proteins are used for their separation, identification, and assay, including the following:

1. ***Molecular size.*** Most proteins are macromolecules having high molecular weights that vary markedly among the proteins. Proteins are separated from smaller molecules by dialysis or ultrafiltration across membranes of specified pore size or by molecular exclusion chromatography (gel filtration). Because of their differing molecular weights, they also are separated by density-gradient ultracentrifugation.
2. ***Differential solubility.*** Loss of solubility is essentially the loss of affinity of the solute for the solvent. The solubility of a protein is affected by the pH, ionic strength, temperature, and dielectric constant of the solvent in which it is placed. Changing the pH of the solvent affects the surface charges of the polar R groups exposed to the solvent; at its pI (net charge zero), a protein in a polar solvent is in its least soluble state because it has the least

affinity for the solvent. Manipulation of ionic strength of the solvent affects the degree of hydration of the protein; in high concentrations, ionic salts compete with protein for water and thus decrease the amount of water available for hydration of the protein molecules. This behavior is the basis of "salting-in" and "salting-out" procedures, the earliest methods for separating and characterizing different proteins and groups of proteins. Raising the temperature affects solubility by decreasing the intramolecular bonding of a protein; loss of secondary and tertiary structure exposes the less polar interior of the protein molecule to the polar medium. Water-miscible neutral organic solvents have dielectric constants that are less than that of water; they suppress the ionization of the surface R groups on the protein and thereby decrease its solubility. Manipulation of solvent character and composition in such ways is often useful in analyses of biological protein-containing fluids.

3. ***Electrical charge.*** The effect of pH to confer, enhance, or change the surface charges on a protein can create, in a mixture of different proteins, various species of different charge-mass ratios, which migrate at different rates in an electrical field; electrophoresis and isoelectric focusing are based on this behavior. Ion-exchange chromatography is based on electrostatic interactions of charged proteins with oppositely charged solid media.
4. ***Adsorption on finely divided inert materials.*** These materials offer a large surface area for interaction with protein. Adsorption of protein on charcoal, a nonpolar substance, presumably occurs by hydrophobic interaction and can be used to separate proteins from a fluid matrix. Adsorption on polar substances such as silica, alumina, or hydroxyapatite depends on ionic interactions or hydrogen bonding; these substances can be used with buffer *elution* in chromatographic separations.
5. ***Specific binding to antibodies, coenzymes, or hormone receptors.*** The unique property of a protein to recognize and bind to complementary antibodies with high specificity is the basis for immunochemical assays (see Chapter 9). Proteins can also be separated by affinity chromatography, in which a ligand attached to a solid medium provides high selectivity (see Chapter 6).

Plasma Proteins

The proteins most amenable to routine laboratory evaluation are those in blood, urine, CSF, amniotic fluid, saliva, feces, and peritoneal or pleural fluids. With few exceptions, the proteins found in all of these are derived from blood plasma. The following discussion is limited to (1) the most abundant *plasma* proteins, (2) changes of their concentrations in the most accessible body fluids, and (3) a few of the analytical techniques used to measure them.

Most plasma proteins, with the exception of immunoglobulins and protein hormones, are synthesized primarily in the liver. They are secreted by the hepatocytes into the spaces of Disse and then move into the bloodstream through the hepatic sinusoids, which open into the central veins of the liver. Plasma proteins circulate in the blood and between the blood and the extracellular tissue spaces; their movement occurs not only by passive diffusion through junctions between capillary endothelial cells but by active transport mechanisms and by pinocytosis and exocytosis. Because of this movement, extravascular fluids normally contain small amounts of many plasma proteins. Differences in molecular size and charge among proteins and the specificity of transport mechanisms account for differences in kind and proportions of individual proteins in different fluids. Disease often alters the amounts of plasma proteins in body fluids in characteristic ways. Most plasma proteins are catabolized in the liver; for some, the signal that marks them for degradation appears to be the loss of part or all of their sialic acid content.

Table 20-3 lists the principal plasma proteins and their half-lives, pI, molecular weights, and preferred method of analysis; the individual proteins are listed in the order of their electrophoretic mobilities in agarose gels at pH 8.6. These proteins are described later in this chapter; other chapters in this book describe many more proteins: enzymes (see Chapter 21); lipoproteins (see Chapter 26); hormones (see Chapter 28); and hemoglobin, fibrinogen, and other coagulation proteins (see Chapter 31). The interim consensus reference intervals for 14 plasma proteins are listed in Table 20-4, pending the publication of more definitive intervals.[28]

Our knowledge of body fluid proteins and their alterations in health and disease has grown rapidly in the past few decades. Some of the alterations have a genetic origin; many more reflect physiological or pathological processes.[59] In many cases, the association of a specific disease with a specific pattern of altered proteins remains empirical, simply because the cause and effect relationships remain unknown. In many instances, laboratory analyses detect and evaluate these variations reliably, but they must always be considered in the context of clinical findings and in terms of all the factors, technical and biological, that may affect the results.

Rates of hepatic synthesis of many plasma proteins are affected by a patient's endocrine status. The effects of some steroid hormones on individual plasma protein levels are given in Table 20-5. The plasma protein levels characteristic of a specific disease may therefore be complicated by the steroid status of a patient and by an inflammatory acute phase reaction. The abnormal steroid status may be the result of an intrinsic hormonal disorder or of treatment with steroid hormones, as in inflammation.

Several of the proteins in Table 20-3 are acute phase reactants (APR) with the concentrations of α_1-antitrypsin (AAT), α_1-acid glycoprotein (AAG), haptoglobin (Hp), ceruloplasmin, C4, C3, procalcitonin (PCT), and serum amyloid A (SAA) increasing in most forms of inflammation; these are called *positive APR*. Others, such as transthyretin

TABLE 20-3 Properties of Selected Plasma Proteins

Electrophoretic Region	Protein	Half-Life	pI	MW (daltons)	Preferred Analysis Method	Comments
	Retinol-binding protein (RBP)	12 hr		21,000	IN, IT, RID	Transports retinol (vitamin A); complexed to TTR
	Transthyretin (TTR)	48 hr	4.7	54,980	IN, IT, RID	Transports thyroid hormones, RBP
	Albumin	15-19 days	4-5.8	66,300	IN, IT, RID, dipstick	A general transport protein; maintains plasma osmotic pressure
α_1	α_1-Antitrypsin (AAT)	4 days	4.8	51,000	IN, IT	Protease inhibitor, especially elastase
	α_1-Acid glycoprotein (AAG, orosomucoid)	5 days	2.7-4	40,000	IN, IT, RID	Function obscure; binds cationic drugs and hormones
	α_1-Fetoprotein (AFP)			69,000	RIA, EIA, fluorescence polarization	Principal fetal protein; albumin analogue
α_2	Haptoglobin (Hp, HAP)	2 days	4.1*	85,000-840,000	IN, IT	Binds hemoglobin; reduced by hemolysis
	α_2-Macroglobulin (AMG)	5 days	5.4	720,000	IN, IT, RID	General proteolytic enzyme inhibitor
	Ceruloplasmin (CER)	4.5 days	4.4	132,000	IN, IT, RID, enzymatic	Oxidant-antioxidant (especially for iron)
β_1	Transferrin (Tf, siderophilin)	7 days	5.7	79,600	IN, IT, RID	Transports iron
	C4			206,000	IN, IT, RID	Complement factor
β_2	C3			180,000	IN, IT, RID	Complement factor
	β_2-Microglobulin (BMG)			11,800	RIA, EIA	Used to test renal tubular function; elevated in

TABLE 20-3 Properties of Selected Plasma Proteins—*Continued*

Electrophoretic Region	Protein	Half-Life	pI	MW (daltons)	Preferred Analysis Method	Comments
						lymphocytosis or lymphocyte breakdown
γ	IgG	24 days	6-7.3	144,000-150,000	IN, IT, immunofixation	Antibody
	IgA	6 days		~160,000	IN, IT, immunofixation	Antibody
	IgM	5 days		900,000	Nephelometry, immunofixation	Antibody
	C-reactive protein (CRP)		6.2	~115,000	RID, RIA, IN, IT, homogeneous enzyme immunoassay	Nonspecific defense against infectious agents; removal of cellular debris

IN, Immunonephelometry; *IT,* immunoturbidimetry; *RID,* radial immunodiffusion; *RIA,* radioimmunoassay.
*For Hp 1-1 phenotype.

TABLE 20-4 Interim Consensus Reference Intervals for 14 Plasma Proteins in Human Serum Referenced to CRM 470

Protein	g/L	mg/dL
α_1-Acid glycoprotein	0.5-1.2	50-120
Albumin	35-52	3500-5200
α_1-Antitrypsin	0.9-2.0	90-200
C3*	0.9-1.8*	90-180*
C4	0.1-0.4	10-40
Ceruloplasmin	0.2-0.6	20-60
C-reactive protein	<5	<0.5
Haptoglobin	0.3-2.0	30-200
IgA	0.7-4.0	70-400
IgG	7-16	700-1600
IgM	0.4-2.3	40-230
Transthyretin (prealbumin)	0.2-0.4	20-40
α_2-Macroglobulin	1.3-3.0	130-300
Transferrin	2.0-3.6	200-360

From Dati F, Schumann G, Thomas L, et al. Consensus of a group of professional societies and diagnostic companies on guidelines for interim reference ranges for 14 proteins in serum based on the standardization against the IFCC/BCR/CAP reference material (CRM 470). Eur J Clin Chem Clin Biochem 1996; 34:517-20.
These values are applicable only to adults between 20 and 60 years of age.
*Values are slightly lower in fresh samples (assayed <8 hr after draw).

TABLE 20-5 Effects of Steroid Hormones on Plasma Protein Concentrations

	Corticoid	Androgen	Estrogen
Prealbumin	+	+	–
Albumin	–	N	–
α_1-Lipoprotein	N	–	++
α_1-Acid glycoprotein	+	+	–
α_1-Antitrypsin	N	+	++
Haptoglobin	+	++	–
Ceruloplasmin	N	N	+++
Transferrin	N	+	+
β-Lipoprotein	++	+	N
IgG	–	N	–

Modified from Whicher JT. Abnormalities of plasma proteins. In: Williams DL, Marks V, editors. Biochemistry in clinical practice. London: William Heinemann, 1983:221-50.
+, Increase; *N,* no change; –, decrease.

(prealbumin), albumin, and transferrin in particular, are *negative APR,* which have levels decreasing with inflammation. Associated disorders include surgery, trauma, myocardial infarction, bacterial infections, and many tumors. Presumably the APR all play a part in the very complex defensive process of inflammation, particularly in complement activation and in control of enzyme activity. The acute phase reaction is a nonspecific reaction to inflammation, comparable with the increase in temperature or leukocyte count, and is not diagnostic for any given disease. Most of the changes are triggered by cytokines released from the site of injury (see Chapter 22).

Plasma levels of the individual acute phase proteins rise at different rates—first, CRP, SAA, and α_1-antichy-

motrypsin; after the first 12 hours, AAG; after 24 to 48 hours, AAT, Hp, C4, and fibrinogen; and finally C3 and Cp. All reach their maximums within 2 to 5 days following an acute insult and then decrease in the same order as above. Although these changes do not aid in the diagnosis of the cause of inflammation, measurement of those proteins with the largest and earliest rises (e.g., CRP and SAA) can be useful in monitoring the progress of an inflammatory reaction or its response to treatment. In a 2003 study, procalcitonin and SAA levels were found to be more sensitive than CRP for detecting bacterial infection, although SAA levels also rise in most viral infections and are thus less specific.[69]

Individual plasma proteins are discussed in the following sections. They are listed in alphabetical order.

Albumin

The name "albumin" refers to the white precipitate (mostly albumin) formed during the boiling of acidic urine (L. *albus* = white). Normally, albumin is the most abundant plasma protein from midgestation until death, accounting for approximately one half of the plasma protein mass. It is a relatively small protein (molecular mass 66.3 kDa) with a globular conformation, permitting equilibration across the vascular and glomerular basement membranes. Because of this and its high plasma concentration, albumin is a significant component of most extravascular body fluids, including CSF, interstitial fluid, urine, and, during pregnancy, amniotic fluid. Indeed, approximately 60% of the total body albumin is in the extravascular space.[81]

Biochemistry

Albumin has a single polypeptide chain of 580 amino acids, with 17 intrachain S-S bonds aligned in a multiple loop structure. Albumin is one of only a few plasma proteins with no carbohydrate side chains. It is a very stable protein with a high net negative charge at physiological pH and, partly as a result, very high solubility in water. There is one free —SH group at position 34 that reacts completely with thiol compounds, such as cysteine, at physiological pH.[81]

Albumin is synthesized primarily by the hepatic parenchymal cells except in early fetal life, when it is synthesized largely by the yolk sac. The synthetic reserve of the liver is enormous; in nephrotic syndrome, it may be 300% or more of normal. The synthetic rate is controlled primarily by colloidal osmotic pressure (COP) and secondarily by protein intake.[81,92] Synthesis is decreased by inflammatory cytokines,[93] and release (but not synthesis) is decreased by hypokalemia.[92] Catabolism occurs primarily by pinocytosis by all tissue, with lysosomal catabolism of the protein and use of the resulting free amino acids for synthesis of cellular proteins. The rate of pinocytosis is proportional to the local tissue metabolic rate. Small amounts (10% to 20% of the total catabolized) are also lost into the gastrointestinal tract and the glomerular filtrate.[81] Nearly all of the protein in the glomerular filtrate is reabsorbed and catabolized by the proximal renal tubular cells, resulting in a very low concentration in normal excreted urine. The normal plasma half-life of albumin is 15 to 19 days.

Function

The primary function of albumin is generally considered to be the maintenance of COP in both the vascular and extravascular spaces. This is supported teleologically by the fact that its synthesis is regulated primarily by COP. If the plasma albumin level rises or falls, the concentration in extravascular spaces rapidly equilibrates with plasma to compensate for this. As discussed later, most analbuminemic individuals have little or no edema, in part because of this equilibration and in part by increased synthesis of other proteins.

The presence of many charged surface groups plus many specific binding sites, both ionic and hydrophobic, gives albumin the ability to bind and transport a large number of compounds. These include free fatty acids, phospholipids, cholesterol, metallic ions, amino acids, drugs, hormones, and bilirubin, among many others. Albumin is essential for the metabolism and detoxification of many of these, although analbuminemic individuals are significantly affected only by the absence of albumin's lipid and calcium transport properties. High levels of albumin are partially protective against atherosclerosis, probably because of its promotion of cholesterol efflux from fibroblasts and other cells.[41] Albumin binds many hormones, such as triiodothyronine or T_3, but with lower affinity than other proteins (in this case, thyroxine-binding globulin and transthyretin, or prealbumin). It appears to act as a reservoir to ensure that only the physiological amount of free hormone is present, while permitting the rapid release of additional hormone as the free hormone is used or excreted.[81]

Albumin also functions as an amino acid source for peripheral tissue. After ingestion and absorption of amino acid–containing foods, albumin transports them to tissue. In addition, pinocytosed albumin itself can serve as a source of amino acids for tissue. The synthesis of albumin by the liver increases after meals, apparently in an attempt to prevent loss or catabolism of essential amino acids. Complexing by albumin appears to be necessary for the transport of some amino acids across membranes, in particular the transport of tryptophan across the blood-brain barrier.

Other important functions of albumin include the following:

1. Albumin is an important component of plasma antioxidant activity.
2. Albumin acts as a buffer, especially in nonphysiological conditions.
3. The binding of albumin to endothelial membrane-associated glycoproteins increases capillary permeability to small proteins that are important for metabolism in the extravascular space.

4. Albumin inhibits leukotriene and actin production, thus reducing the inflammatory response of platelets and neutrophils.

Clinical Significance

Increased Plasma Levels. Measurably increased levels of albumin are seen only in acute dehydration. As a result, the finding of elevated values has little clinical utility. As noted previously, synthetic rate and intravascular-extravascular shifts usually occur fairly rapidly to stabilize relative osmotic pressures.

Decreased Plasma Levels. Decreased levels of albumin may result from decreased synthesis, increased catabolism (use or loss), or combinations of these. Decreased synthesis may be primary or genetic (as in analbuminemia) or acquired (as in inflammatory processes). Hypoalbuminemia may result in underestimation of the anion gap when evaluating fluid and electrolyte status.[31]

Analbuminemia. Only 20 or so families with inherited analbuminemia have been reported, attesting to the protein's physiological importance.[57] Although affected individuals have plasma albumin levels less than 0.5 g/L (about 1% of normal), they were originally reported to be clinically normal except for mild edema (usually none before the second to fourth decades of life) and altered lipid metabolism. In 1996, the presence of lipodystrophy in women and osteoporosis, hypotension, arcus lipoides corneae, and xanthomatosis in some patients was first reported.[57] In one patient, ankle edema disappeared rapidly with intravenous albumin infusion; however, she developed signs of hypocalcemia during infusions. The infusions did not affect her lipodystrophy. In spite of the lipid abnormalities in affected individuals, there is no increased risk for atherosclerosis. The plasma half-life of infused albumin in affected individuals is 50 to 60 days or approximately three times normal.

Inflammation. Inflammatory disorders, both acute and chronic, are the most common cause of decreased plasma albumin levels. At least four factors are responsible for the decreases: (1) hemodilution; (2) loss into the extravascular space caused by increased vascular permeability; (3) increased consumption by cells locally; and (4) decreased synthesis as the result of direct inhibition by cytokines (see Chapter 22) and by increased COP. This increase in plasma COP results acutely from increased levels of the positive APR; chronically, it results most often from increased levels of immunoglobulins.[81,93]

Hepatic Disease. The liver retains the ability to synthesize even increased amounts of albumin until parenchymal damage or loss is severe, with the loss of 50% to 95% of function. Thus other mechanisms are responsible for the decreased levels seen in most cases of hepatocellular disease.[45] These include, among others, increased immunoglobulin levels, third space loss (extravasation into the extravascular space), and direct inhibition of synthesis by toxins, including alcohol. The inhibitory effect of alcohol is lessened by adequate levels of tryptophan. Albumin levels do not correlate well with severity, prognosis, or level of total hepatic function in either acute hepatitis or cirrhosis.

Urinary Loss. Because albumin is relatively small and globular, relatively large amounts filter into the glomerular urine in spite of its acidic charge at physiological pH. Filtration is increased if acidic groups are blocked (e.g., by glycosylation in patients with diabetes mellitus). Most of the filtered albumin is normally reabsorbed by the proximal tubular cells, but normal excreted urine still contains up to 20 mg albumin/g creatinine, or 20 mg albumin/L urine. Excretion above this amount suggests either increased glomerular filtration (as seen in the nephrotic syndrome), proximal tubular damage, hematuria, or combinations of these. Increased filtration may be seen with "physiological" states, such as physical exercise and fever; therefore urinary albumin should preferably be assayed under controlled conditions and repeated if there is a question.

Although there is still debate about its significance, mildly increased excretion (20 to 300 mg/L) of albumin, so-called *microalbuminuria* (more correctly termed *minimal albuminuria* or *paucialbuminuria*), appears to be a predictor of future development of clinical renal disease in patients with hypertension or diabetes mellitus. It is important to remember that tubular and postrenal causes of albuminuria may also be present in association with these disorders.

Except for hereditary analbuminemia, the lowest levels of plasma albumin are seen in patients with active *nephrotic syndrome.* In this disorder, the glomerular leakage of all proteins is increased, but sieving is usually retained (i.e., small proteins are lost disproportionately). The liver compensates by marked increase in production of many proteins, including albumin. As a result of the sieving and increased production, the concentrations of proteins with high molecular mass, such as α_2-macroglobulin (AMG), larger isotypes of Hp (phenotypes 2-1 and 2-2), and the apolipoproteins are elevated more or less proportionately to the loss of albumin and other small proteins. The resulting electrophoretic pattern is classic, with markedly elevated α_2-globulins (AMG, plus Hp unless Hp 1-1) and lipoproteins, but reductions in most other proteins.

Urinary albumin: α_1-microglobulin and albumin:IgG ratios have been proposed as a means of differentiating among nephropathies and glomerulopathies associated with proteinuria.[52]

Gastrointestinal Loss. Inflammatory disease of the intestinal tract, such as acute viral gastroenteritis, is associated with increased loss of albumin. This is usually of little concern unless the loss is excessive or long lived. However, protein-losing enteropathy may result in losses as great as those seen in the nephrotic syndrome. If protein-losing enteropathy is secondary to lymphangiectasis, larger proteins—especially the immunoglobulins—may be lost in large amounts.

Protein Calorie Malnutrition. Albumin levels have been recommended as a means of detecting and monitoring protein calorie malnutrition, because levels vary directly with adequacy of intake. However, the response of albumin to increased or decreased protein ingestion is relatively slow, in part because of its relatively long half-life (15 to 19 days). Also, as noted previously, the most common cause of low levels is acute or chronic inflammation. Unless inflammation and other causes of increased COP are ruled out, albumin levels do not correlate well with degree of malnutrition.[55]

Edema and Ascites. Edema and ascites rarely are the result of decreased plasma albumin levels per se. Usually they are secondary to increased vascular permeability, which permits the loss of albumin into these spaces. The albumin levels in these fluids vary from very low to higher than those in plasma, the latter in particular with certain forms of ascites.[46] Even with low concentrations, either disorder may be massive enough to contain a substantial portion of the total body albumin.

In patients with edema or ascites associated with low plasma albumin, the effect of albumin infusion is very transient because of rapid equilibration with the extravascular fluid. The only situation in which infusion is usually beneficial is in acute hypovolemic shock; in this case, rapid infusion may result in hypocalcemic tetany, because albumin binds Ca^{2+} with relatively high affinity.

Genetic Aspects

Albumin is coded by a gene on the long arm of chromosome 4, closely linked to the genes for α-fetoprotein (AFP) and vitamin D binding globulin (or Gc globulin), both of which share extensive sequence homology with albumin.[5] Inherited analbuminemia has been reported in a few families. Inheritance is autosomal codominant, with heterozygotes having low normal to reduced levels. Low levels (5% to 10% of normal) are also seen with Alb Hawkes Bay, an electrophoretic variant with a cys → phe substitution at position 177, resulting in abnormal disulfide bonding.[6]

More than 80 additional alleles associated with altered structure but normal concentrations of albumin have been reported. All are inherited in autosomal codominant fashion, with both gene products expressed in approximately equal amounts. Many of the isotypes have altered electrophoretic migration, resulting in so-called *bisalbuminemia.* However, electrophoretic patterns must be interpreted with caution, because bound drugs and metabolites may also change albumin's electrophoretic migration. The common, or wild, type is Alb A; in whites of European descent, the second most frequent variant is Alb B (~1 in 1000 to 10,000 depending on ethnic origin). Alb B has a more cathodal electrophoretic migration because of a glu → lys substitution.

At least two variants are associated with dimer formation, which also results in more cathodal migration. However, they are usually seen as a cathodal blur instead of a distinct, separate band, as is the case with Alb B. The degree of dimer formation and of complexing with other proteins, such as IgA, with these variant albumins varies with storage conditions, pH, and concentration of low molecular weight —SH compounds, such as glutathione; hence the same serum sample may appear different on electrophoresis at different times. Perhaps the most important laboratory consequence of these variants is the formation of complexes with AAT, resulting in apparent deficiency of this protein on electrophoretic patterns. However, quantification of AAT by immunochemical methods is normal.

The function of most albumin isoforms is normal, although some have abnormal binding affinities for thyroxine (T_4). Binding may be increased, as in familial dysalbuminemic hyperthyroxinemia,[116] or decreased.[1] Individuals with familial dysalbuminemic hyperthyroxinemia are euthyroid but have elevated serum T_4 and free T_4 index; the variant albumin comigrates with Alb A. Two glycosylated variants, Alb Redhill and Alb Casebrook, have altered fatty acid binding properties.

Laboratory Considerations

Plasma and Serum. Most clinical laboratories assay albumin in plasma or serum samples by automated dye-binding methods, which rely on a shift in the absorption spectrum of such dyes as bromcresol green (BCG) or purple (BCP) upon binding to proteins. The affinity of these dyes is much higher for albumin than for other proteins, so specificity is increased if only the initial rate of binding is used. Monochromatic methods overestimate albumin in the presence of fibrinogen and heparin (e.g., in heparinized plasma or in "serum" from heparinized patients). This interference can be circumvented by using a bichromatic method.[43] Dye-binding assays also tend to be erroneous if the overall serum protein pattern is abnormal (e.g., in liver disease)—situations in which accurate analysis is most desired. BCP binding assays of albumin in ascitic fluid give spuriously high results.[33] Many other ligands, including drugs and metabolites, bind to albumin but usually do not affect dye-binding assays of serum or plasma significantly unless their concentrations are very high. Because of their simplicity and low cost, dye-binding assays are likely to remain the predominant means for assaying albumin.

The use of densitometric scans of electrophoretic patterns, in association with total protein assays, as a means of quantifying albumin is notoriously inaccurate and is discouraged. The problems relate in part to lateral diffusion of relatively small proteins, including albumin, on support media and to nonlinearity secondary to a lack of saturation of albumin dye-binding sites.

Immunochemical methods, especially automated immunoturbidimetry and immunonephelometry, are more accurate and precise than the methods mentioned previously.

Urine. As previously mentioned, the term *albumin* derives from the white precipitate resulting from boiling acidified urine. The sulfosalicylic acid heat test is still used today to test for albuminuria; however, screening is usually

performed by test strips, most of which have lower detection limits of 200 to 300 mg/L. Special strips are now available for detecting microalbuminuria. The immunochemical methods used for serum can assay very low levels of albumin in undiluted urine and are very rapid and precise.

Cerebrospinal Fluid. Immunoturbidimetry and immunonephelometry are also useful for CSF assays.

Reference Intervals

Based on the international protein reference CRM 470, the recommended interim reference interval for albumin in serum of adults 20 to 60 years of age is 35 to 52 g/L (3.5 to 5.2 g/dL).[28] Albumin levels reach adult levels around 20 to 30 weeks of gestation and remain relatively constant until at least 20 years of age. Levels then slowly decrease with age in both sexes. Levels are lower in individuals living in the subtropics and tropics, probably because of higher immunoglobulin levels secondary to infection or parasitic infestation. Levels are very posture dependent, increasing by up to 10% to 15% if the individual is standing.

Alpha$_1$-Acid Glycoprotein (Orosomucoid)

AAG was one of the first plasma glycoproteins to be isolated in the pure state and to be well characterized. Historically, AAG is the major constituent of the seromucoid fraction of plasma, a group of proteins that are precipitated by $HClO_4$ and other strong acids and that are "slimy" on purification ("mucoid" is from Greek *myxa* = slime). The seromucoid fraction has long been of clinical interest because it was one of the first recognized components of the acute phase response.[21]

Biochemistry

AAG contains a high percentage of carbohydrate and a large number of sialic acid residues, giving it a very high net negative charge and high solubility in water. It has a polypeptide chain containing 181 amino acids and a total molecular mass of 40 kDa, of which approximately 45% is carbohydrate (CHO), including 11% to 12% sialic acid. The CHO includes a variable mixture of biantennary, triantennary, and tetraantennary side chains with terminal sialyl residues, resulting in significant microheterogeneity of the intact molecule upon electrophoresis at pH 2.9 or isoelectric focusing. The relative proportions of the different side chains vary with disease states and nutrition, altering their isoelectric points and their reactivity with the lectin concanavalin A. It has also been suggested that changes in glycosylation alter function in vivo.[109]

AAG is synthesized primarily by the hepatic parenchymal cells, but granulocytes and monocytes may also contribute to plasma levels in sepsis. Catabolism is believed to be primarily by removal of desialylated AAG by hepatic asialoglycoprotein receptors. The plasma half-life of intact AAG is ~3 days, whereas that of the desialylated protein is only a few minutes.

Function

Although many functions have been proposed for AAG, its true physiological role still remains unknown. AAG is one of the *lipocalins*, a group of proteins that bind lipophilic substances and share much sequence homology. The lipocalin group also includes retinol-binding protein, β-lactoglobulin, α_{2m}-globulin, α_1-microglobulin (protein HC), bikunin, the chain of complement C8, and inter-α-trypsin inhibitor.[80] AAG has long been known to bind and "inactivate" a large number of basic and lipophilic compounds, including progesterone and related hormones, and the progesterone antagonist RU 486. AAG's binding of progesterone has been proposed to constitute a means of controlling hormonal effects in the fetus. AAG also binds and reduces the bioavailability of many drugs, including propranolol, quinidine, chlorpromazine, cocaine, and benzodiazepines. Most assays for drug levels in plasma or serum assay the total, not just free, drug. If AAG levels are elevated secondary to an acute phase response or corticosteroid therapy, administration of additional drug (and higher blood concentrations) may be necessary to compensate for the increased binding.

Other proposed functions for AAG include down regulation of the immune response, depression of phagocytosis by neutrophils, inhibition of platelet aggregation, inhibition of mitosis, and inhibition of viruses and parasites. In addition, it has been reported to affect collagen fiber formation and to be a cofactor for lipoprotein lipase. It is also essential for maintaining capillary selectivity for passage of albumin and other macromolecules, including in the glomerulus, because of its high negative charge.

Clinical Significance

Various pathological conditions are associated with increased and decreased levels of AAG.

Increased Plasma Levels. Serum AAG increases in inflammation and tissue necrosis and from hormonal effects.

Acute Phase Response. Plasma AAG levels show a threefold to fourfold increase in most conditions associated with inflammation or tissue necrosis, with peak concentrations around 3 to 5 days after the initial insult. AAG may be one of the most reliable indicators of clinical activity of ulcerative colitis.

Hormonal Effects. AAG levels are increased by glucocorticoid hormones, either endogenous (e.g., Cushing's syndrome) or exogenous (as in prednisone or dexamethasone therapy), along with Hp and prealbumin (transthyretin) levels.

Decreased Plasma Levels. Hormonal effects and sieving protein loss are known to decrease AAG levels.

Hormonal Effects. Synthesis and plasma AAG levels are decreased by estrogens.

Sieving Protein Loss. Because of its small molecular size, AAG is lost into the urine in nephrotic syndrome and into gastrointestinal secretions in protein-losing enteropathy.

Genetic Aspects

The presence of different isotypes of the peptide chain of AAG, inherited in autosomal codominant fashion, has long been recognized. There are three genes for AAG in a cluster on chromosome 9q34.3, closely linked to the loci for several other members of the lipocalin family. The originally reported polymorphism (designated *OR*) represented the products of the *ORM1* locus, which accounts for about two thirds of AAG synthesis and most of the isotypic variability. The products of both the *ORM1* and *ORM2* loci can be simultaneously phenotyped by isofocusing of desialylated AAG in immobilized pH gradients containing urea. The variants have no known clinical significance.

Laboratory Considerations

It has been proposed that AAG always be assayed along with haptoglobin when levels of the latter are used to evaluate possible in vitro hemolysis, because hormonal and acute phase effects are similar for the two proteins (see section on Haptoglobin). Although AAG is one of the highest concentration proteins in the α_1-globulin region on routine serum electrophoresis, it does not stain well with protein stains because of its high CHO content. It can be visualized by using periodic acid-Schiff or other carbohydrate stains. AAG can be quantified by all immunochemical methods, including turbidimetry and nephelometry.

Reference Intervals

The proposed interim reference interval for white adolescents and adults is 0.5 to 1.2 g/L (50 to 120 mg/dL), based on CRM 470.[28] Levels at birth are only 20% to 30% of this, but reach approximately adult levels by 6 to 12 months of age.

Alpha$_1$-Antitrypsin

Schultze first described AAT in 1955, later giving it this name because of its inhibition of trypsin. The name "α_1-proteinase inhibitor" was later introduced because of AAT's broad spectrum of inhibition of serine proteases, not just trypsin. Both names are currently used, but AAT is preferred by most clinicians and clinical laboratorians and is used in this chapter.

Biochemistry

AAT has a single polypeptide chain of 394 amino acid residues with three CHO side chains, giving a total molecular mass of ~51 kDa. The active site is contained in a "stressed" reactive loop; on reaction with a serine protease, a small fragment is cleaved, and the remainder of the protein assumes a "relaxed" configuration.[11]

Most if not all plasma AAT is synthesized by the hepatic parenchymal cells, as evidenced by the complete change in phenotype in patients (including those with AAT deficiency) transplanted with livers from individuals with other phenotypes. AAT is an acute phase reactant, with hepatic synthesis and plasma levels rising greatly during inflammatory or necrotic processes. Catabolism occurs by two routes, both primarily in hepatic parenchymal cells: AAT-protease complexes are removed by the serpin-enzyme complex receptors (SEC-R),[79] along with several other serpin-enzyme complexes; in addition, desialylated AAT is removed by asialoglycoprotein receptors. Most proteases complexed with AAT in vivo may be transferred to AMG; the AMG-protease complexes are removed almost immediately by the Kupffer cells of the liver, with a much shorter plasma half-life than AAT-protease complexes.

The normal plasma half-life is 6 to 7 days for the Pi M phenotype; Pi S, and perhaps other variants, has a shorter half-life and secondarily lower plasma levels.

Function

AAT is one of the serpins, or *ser*ine *p*roteinase *in*hibitors, which act as substrates for, then form tetrahedral complexes with the active sites of serine proteases, thus blocking their enzymatic activity. Other members of the serpin superfamily include the proteinase inhibitors α_1-antichymotrypsin, α_2-antiplasmin, antithrombin III, heparin cofactor II, and C1 inhibitor, plus ovalbumin, thyroxine-binding globulin, and other proteins with similar structures but no apparent inhibitory activity. AAT is the second highest concentration proteinase inhibitor in plasma on a mass basis, after AMG; however, AAT has only 7% of the mass of AMG and is by far the highest concentration inhibitor on a molar basis. Its small size allows AAT to pass into all body fluids, whereas AMG is mostly intravascular. AAT inhibits most serine proteases, especially those structurally related to trypsin. It is physiologically most important as an inhibitor of leukocyte elastase, which is released in the process of phagocytosis by polymorphonuclear leukocytes. This enzyme, as its name implies, reacts with elastin in the vascular endothelium and the tracheobronchial tree, in particular. AAT is thus important in the prevention of loss of elastic lung recoil; uninhibited elastase in the bronchial tree can result in the development of emphysema.

AAT may also be a physiologically important inhibitor of leukocyte neutral protease, kallikrein, renin, urokinase, plasmin, and thrombin. It probably does not inhibit leukocyte collagenase (a metalloproteinase), as is often stated; it more likely inhibits a leukocyte protease that activates procollagenase.

Clinical Significance

Increased Plasma Levels. Plasma AAT levels are increased in the acute phase response and with estrogens.

Acute Phase Response. In inflammatory or necrotic processes, serum AAT levels begin to rise after approximately 24 hours and peak at 3 to 4 days if the insult is acute and short lived. Synthesis is stimulated by cytokines, particularly the IL-6 family, and by AAT-elastase complexes taken up via SEC-R. Cytokines induce a broader APR, whereas uptake by the SEC-R induces only AAT synthesis. The acute phase response of AAT probably occurs in an attempt to control

the effects of proteases released in areas of inflammation or necrosis. Inflammation of the hepatic parenchymal cells themselves may be associated with increased serum AAT without the other components of the acute phase response.

Estrogens. The synthesis of AAT is stimulated by estrogens; elevated levels are seen particularly during late pregnancy and during estrogen therapy.

Decreased Plasma Levels. Plasma AAT levels are decreased with genetic deficiency, increased use, and urinary or gastrointestinal loss.

Genetic Deficiency. As noted previously, severe genetic deficiency of AAT (Pi Z or null phenotypes) is associated with a very high risk for development of pulmonary emphysema. In affected individuals, emphysema tends to be primarily in the basilar areas (probably because of gravitational vascular pooling), rather than the more typical disease seen in other forms of emphysema. Onset of disease is also much earlier, with changes beginning in the second to fourth decades of life in 90% of Pi ZZ individuals. The primary mechanism for development of emphysema is the degradation of elastin by leukocyte elastase; this process is increased by air pollution and by cigarette smoking because of recruitment and activation of leukocytes in the lung plus the oxidation of methionine 358 in the active site of AAT, rendering it unable to inhibit elastase.[10] The age of onset of symptomatic emphysema and the median age of death are also earlier in individuals who smoke cigarettes. However, there is much variation in the development and progression of disease, even in smokers. Antioxidants may reduce the deleterious effects of smoking, but smoking cessation is by far the better approach.

A deficiency of α_1-antitrypsin is also associated with diseases of the liver, including neonatal cholestasis or "hepatitis," cirrhosis, and hepatocellular carcinoma. Although cirrhosis may be seen at birth, the so-called neonatal hepatitis syndrome is much more common, with varying degrees of hepatocellular damage but particularly with cholestatic jaundice. Neonatal cholestasis was noted in 11% of Pi ZZ infants in Sweden, with another 6% showing biochemical evidence of hepatic disease but no jaundice.[103] This picture is most commonly seen at 3 to 8 weeks of age and usually regresses after a few weeks. Intrahepatic and extrahepatic bile ducts may be very small, probably because of decreased bile flow, even to the point of patients presenting with a picture similar to biliary atresia. It is important to differentiate these two disorders because mortality is high in Pi ZZ infants subjected to major surgery. In most affected infants, the bile ducts dilate to normal size as the inflammatory process regresses and bile flow increases. In Swedish Pi Z adults, 12% of those admitted to hospitals had liver cirrhosis, and a strong correlation was found between Pi Z AAT and primary liver cancer at autopsy.[34]

The cause of hepatic damage in AAT deficiency is probably multifactorial. Liver disease is most commonly seen in patients with variants that are retained within the endoplasmic reticulum of the hepatic parenchymal cells (e.g., Pi Z and Pi M_{malton}). There does not appear to be a familial propensity for development of liver disease in Pi Z individuals, which argues against the likelihood of a second inherited defect. The hypothesis most commonly cited at present is that the accumulation of AAT itself results in the hepatic damage; this is supported by the fact that transgenic mice with multiple copies of the human Pi Z gene develop hepatic disease. In addition, Perlmutter has proposed that upregulation of AAT synthesis, perhaps through uptake of elastase-AAT complexes by the SEC-R, increases the synthesis and accumulation of AAT in affected livers.[79] Reduced rates of catabolism of retained intracellular AAT may also be involved. However, the degree of liver disease does not correlate with the amount of intracellular AAT. Many infants with neonatal cholestasis have very little demonstrable intracellular AAT, and many older children and adults have massive accumulations of AAT but no other hepatic damage. Therefore other factors must be involved.

There is evidence supporting a role for hepatic damage by intravascular proteases in the pathogenesis of neonatal hepatic disease, as reviewed in the previous edition of this textbook.[56] The AAT deposits in the hepatic endoplasmic reticulum do not bind normally to calnexin, one of the chaperones for protein synthesis and release[77]; it is known that proteolytic enzymes reduce the activity of intracellular, membrane-bound proteins involved in metabolic processes. An additional component in congenital and neonatal hepatic disease may be exposure to maternal estrogens, which increase susceptibility to damage from hepatitis viral infections and some toxins.

Several other disorders have been reported in association with AAT deficiency, although many of these may be no more than chance occurrences. However, it appears that the risk for development of systemic vasculitic disease, including Wegener's granulomatosis and Henoch-Schönlein purpura, may be increased in deficient individuals.

Increased Utilization. Secondarily low levels of AAT are seen in the neonatal respiratory distress syndrome, severe neonatal hepatitis, and severe preterminal disease of the pancreas. In nonfatal pancreatitis, levels increase along with those of other APR, and increased levels of complexes with trypsin are probably a better marker for use in either differential diagnosis or prognosis in patients with possible pancreatitis.

Urinary or Gastrointestinal Loss. Because of its small size, AAT diffuses into the glomerular urine and into the gastrointestinal tract; however, AAT is not seen in the excreted urine unless there is damage to the proximal tubular cells or marked overflow proteinuria, as in the nephrotic syndrome. In the latter case, the serum level of AAT may be depressed, especially in the absence of an acute phase reaction. AAT is normally present in the excreted stool, mostly complexed to pancreatic trypsin and elastase. In protein-losing enteropathies, the loss may be greatly increased.

Genetic Aspects

The gene locus for AAT (*PI*, for protease inhibitor) is located on chromosome 14q32.1, just distal to the loci for the immunoglobulin heavy chains and closely linked to the loci for the serpins α_1-antichymotrypsin, protein C inhibitor, and corticosteroid-binding globulin.[9] It is a very polymorphic locus. There are more than 75 distinct genetic variants or isotypes of AAT, designated as Pi (pronounced *pee eye*) plus letters from B to Z in order of decreasing electrophoretic mobility—B being the most anodal variant. Numbers or subscripted place names are used to indicate subtypes (e.g., Pi M1 and Pi M_{malton}), and null for either deleted or nonproducing alleles.

Several of the variants are associated with reduced plasma levels, compared with the wild Pi M variant, including the following: Pi P 25%, Pi S 60%, Pi W 80%, Pi Z 15%, and Pi null 0%. Pi Z is most common in northern Europeans, and Pi S is most common in southwestern Europe. Pi Z, clinically the most important deficiency variant, has a lys → glu substitution at position 342, whereas Pi S has a 264 glu → val substitution. There are several known mutations resulting in Pi null, but all are rare. The concentrations and the variants are codominant; therefore an individual with Pi MZ, for example, would normally have a level ~58% of the normal Pi MM level [(100 + 15)/2].

Pi Z, Pi S_{iiyama}, Pi M_{malton}, and Pi M_{duarte} are synthesized by the liver in relatively normal amounts but are only partially secreted, resulting in accumulation within the endoplasmic reticulum of hepatic parenchymal cells and low plasma levels. As a result of a glu → lys substitution in Pi Z, the reactive center loop on one molecule can insert into the β-pleated sheet of a second molecule, resulting in polymerization and retention within the pre-Golgi endoplasmic reticulum. Similar alterations have been shown to be present in Pi S_{iiyama} and Pi M_{malton}.[68] The amino acid substitution and altered molecular folding may also inhibit attachment of CHO side chains, which are necessary for normal secretion by the hepatic parenchymal cells. The retained AAT is seen as "globules" that are eosinophilic and periodic-acid Schiff positive and that react with antibodies to AAT, as shown by immunofluorescence or immunoperoxidase staining of liver sections.

One variant, Pi $M_{pittsburgh}$, has a met → arg substitution at position 358, resulting in a greatly decreased inhibitory activity for elastase but increased activity against several clotting enzymes, including thrombin and kallikrein. Heterozygotes for this variant have a bleeding disorder because of its anticoagulant effects.[96]

Many variants with relatively normal concentrations are apparent on routine clinical electrophoresis; the most common of these are Pi F, Pi X, and Pi V. The low concentration variants should be suspected if the α_1-globulin band appears less intense than normal. As noted in the section on albumin, dimerizing variants of albumin may form complexes with normal AAT variants, resulting in an apparent deficiency of AAT; however, quantification in this case reveals normal levels. If AAT deficiency is suspected by electrophoresis or by quantification, phenotyping may be indicated, particularly if the patient has hepatic or pulmonary disease. Phenotyping is now most often performed by isoelectric focusing in narrow pH range ampholytes (discussed later in this chapter). Genotyping (by deoxyribonucleic acid [DNA] analysis) is also currently in use, particularly for detection of deficiency variants.

Laboratory Considerations

AAT is the major constituent of the α_1-globulin band on routine clinical serum electrophoresis. The two other relatively high concentration α_1-globulins, AAG and α-lipoprotein, do not stain well with peptide stains because of their high contents of CHO and lipid, respectively. Some genetic variants of AAT may be detectable by visual examination of the electrophoresis pattern because of altered mobility or decreased concentration.

There are five to eight AAT bands on either acid gel electrophoresis or isoelectric focusing (pIs approximately 4.2 to 4.9, depending on the genetic phenotype), as shown in Figure 20-3. The microheterogeneity within a single genetic variant results primarily from differences in CHO content and, in the case of the two most cathodal bands, absence of the first five amino acids of the peptide chain.

AAT can be quantified by all immunochemical methods, with immunoturbidimetry and immunonephelometry the most commonly used methods. Because it constitutes about 90% of the serum inhibition of trypsin or elastase activity against small substrates, such as benzoyl-DL-arginine *p*-nitroanilide, it can also be semiquantified by the inhibitory capacity of serum for these enzymes; however, this assay is not specific for AAT.

Leukocyte proteases may be released if serum is allowed to sit on the clot too long after blood drawing. These proteases then form complexes with AAT, altering both electrophoretic mobility and in some cases immunochemical quantification. Bacterial contamination and release of

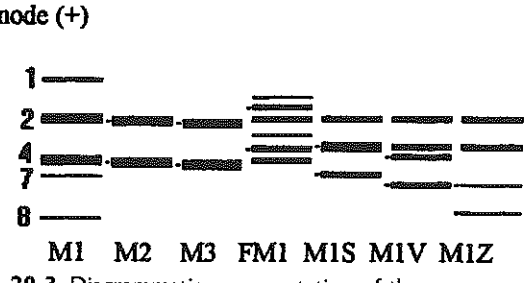


Figure 20-3 Diagrammatic representation of the common variants of α_1-antitrypsin, as demonstrated by isoelectric focusing. The five major bands are shown for M1, but only the 2 and 4 bands for the other variants (with dots to the left of each). Variants F, S, V, and Z are shown in combination with M1 for clarity's sake. If cysteine is added to the samples before focusing, the F-2 and F-4 bands shift to the locations of the faint bands.

bacterial proteases can have a similar effect. Serum should be separated from the retracted clot as soon as possible and stored aseptically at 4 °C (for up to 3 to 4 days) or at −70 °C (for long-term storage).

Reference Intervals

AAT levels remain relatively constant throughout life, from the neonatal period until old age. For adults, the recommended consensus reference interval, based on CRM 470, is 0.9 to 2.0 g/L (90 to 200 mg/dL) for individuals with the Pi MM phenotype,[28] with a median of approximately 1.3 g/L. Levels are slightly higher in women in the childbearing years and in elderly individuals of both sexes. Levels are also higher in inflammatory disorders, malignancy, or trauma, and in women who are pregnant, on estrogen therapy, or taking oral contraceptive pills. Neonates have higher levels, possibly because of maternal estrogen. Individuals with levels below 60 to 70 mg/dL should be phenotyped, especially if they or family members have diseases that may be associated with AAT deficiency.

Alpha$_2$-Macroglobulin

Like the serpins, AMG is a proteinase inhibitor. It is unlike the serpins in many aspects, however. First, it is a very large molecule, with a molecular mass of ~725 kDa. As a result, only very small amounts diffuse out of the plasma space. Second, it acts as a substrate for proteases but does not block their active sites; instead, it "enfolds" the still-active proteases to block access of proteins but not small substrates. Third, it inhibits many different classes of proteinases, including those with serine, cysteine, and metal ions in their proteolytic sites. Fourth, it is structurally related to pregnancy zone protein and to the complement components C3, C4, and C5 rather than to the serpins. Like these proteins, it contains an intrachain thiol ester bond that is necessary for activity and the breaking of which results in a conformational change of the peptide chain.

Biochemistry

A molecule of AMG contains four identical polypeptide chains, present as a pair of dimer subunits. The dimers are covalently linked by disulfide bonds, whereas the pairs are held together by noncovalent bonds. The dimer is the active unit; one molecule of AMG can therefore bind up to two protease molecules. Each monomer contains both the thiol ester mentioned previously and a "bait" site, both of which are essential for inhibitory activity. After the bait site reacts with a protease, the thiol ester is activated and may form covalent bonds with lysine residues on the protease, thus immobilizing it. However, covalent binding is not essential for steric capture and inhibition of proteases.[101]

AMG is synthesized primarily by hepatic parenchymal cells. Catabolism is via two primary routes: once the thiol ester bond is split, AMG—regardless of whether complexed to a protease—is rapidly removed by a hepatic receptor that also acts to remove low-density lipoprotein. Desialylated AMG, like AAT and Cp, is removed by the asialoglycoprotein receptors on hepatocytes. The normal half-life of the intact protein is several days, whereas that of either of these two forms is only a few minutes.

Function

AMG is involved in the primary or secondary ("backup") inhibition of enzymes in the kinin, complement, coagulation, and fibrinolytic pathways. In addition, it acts as a transfer receptor for proteinases complexed to serpins (e.g., elastase-AAT); the AMG-enzyme complexes are then rapidly removed by receptors, as noted earlier.

Oxidation dissociates AMG tetramers into dysfunctional dimers. Thus as is the case for AAT and other serpins, inhibitory activity is reduced or eradicated by increased levels of oxidants (such as those from cigarette smoke or from neutrophils) or decreased levels of physiological antioxidants.

In addition to its critical role as a proteinase inhibitor, AMG transports a large number of small peptides, such as cytokines and growth factors (including insulin and growth hormone), and divalent cations, particularly zinc. Insulin binds covalently to the γ-glutamyl group that is activated from the thiol ester during protease reaction with AMG. Both the native and protease-reacted forms bind cytokines. Binding of these small ligands may be important to prevent diffusional loss or to permit or facilitate cell receptor binding and uptake of them; however, AMG's actual physiological importance as a transport protein is not known.

AMG is also believed to modulate immunological and inflammatory reactions. Complexing of cytokines to protease-reacted AMG reduces cytokine-mediated hepatic production of APR. It, along with AAT, inhibits H_2O_2 release by polymorphonuclear leukocytes; at the same time, it enhances phagocytosis of streptococci and perhaps other organisms.

The physiological importance of AMG is indicated by the fact that no individuals with complete genetic deficiency have been described, whereas total or near-total deficiencies have been described for most other plasma proteins.

Clinical Significance

Increased Plasma Levels. Increased plasma levels of AMG are affected by hormonal effects and age, and seen in the nephrotic syndrome.

Hormonal Effects. Synthesis and plasma levels of AMG are increased by estrogens; women of childbearing age have higher levels than men of the same ages.

Age. Synthesis levels in infants and children are up to three times adult levels, perhaps as a protective mechanism against increased exposure to intestinal proteases in infancy and bacterial or leukocytic proteases during childhood. The high levels may also be responsible in part for the delay in development of clinical signs and symptoms until after puberty in most individuals with either antithrombin III or C1 inhibitor deficiency.

Nephrotic Syndrome. Synthesis levels are increased in the nephrotic syndrome, in part because of volume loss secondary to decreased plasma oncotic osmotic pressure and in part because of increased synthesis of all proteins to compensate for protein loss by the kidneys. The elevated AMG levels partially compensate physiologically for renal loss of lower molecular weight proteinase inhibitors.[58]

Decreased Plasma Levels. Decreased plasma levels of AMG result from various genetic conditions, the acute phase response, pancreatitis, *and* prostatic carcinoma.

Genetic. See Genetic Aspects, later in this chapter.

Acute Phase Response. Synthesis is decreased by IL-1, in parallel with albumin, accounting in part (along with hemodilution) for the mildly decreased levels seen in acute inflammation.

Pancreatitis. In severe attacks of acute pancreatitis, plasma levels of antithrombin III and AMG may be markedly depressed; other inhibitors are normal or increased, and protease-antiprotease complexes are increased. In the peritoneal fluid, all major protease inhibitors are decreased or absent.

Prostatic Carcinoma. Plasma levels of AMG are depressed pretreatment in advanced carcinoma of the prostate and return to normal with successful treatment. AMG binds to prostate-specific antigen (PSA), and levels of the complexes are elevated in plasma during active disease, as is the case for PSA-α_1-antichymotrypsin complexes. In vitro, PSA added to serum has a higher affinity for AMG than for α_1-antichymotrypsin. In vivo, the complexes are probably removed very rapidly by the liver, as are other protease complexes with AMG; usually, free PSA and PSA-α_1-antichymotrypsin are the only forms detected.

Decreased Levels in Extracellular Fluids. Body fluids other than plasma—including extracellular fluid, urine, and CSF—normally contain very low levels of AMG, because of its large molecular size. However, there are several components to the blood-CSF barrier, with a few large pinocytic vesicles transporting proteins up to 1500 Å into the CSF.[67] In some polyneuropathies, the number of these vesicles and the CSF levels of AMG are increased. If there is partial or complete breakdown of the barrier, as in meningitis, or bleeding into the subdural space, levels are also increased. The level of AMG alone, or its relationship to levels of albumin and IgG, may therefore be helpful in differential diagnosis of neurological disorders or of elevated CSF protein. In patients with bacterial meningitis, CSF AMG levels are on average 15 times higher than is the case with nonbacterial meningitis.[87] CSF levels of AMG normally increase with age, suggesting that partial but progressive breakdown of the blood-CSF barrier occurs with aging. Bleeding into the CSF also raises levels in this fluid.

Urinary levels are slightly elevated in the nephrotic syndrome. Levels are higher in malignant ascitic fluid than in nonmalignant ascitic fluid. Increased permeability probably accounts for locally increased levels in areas of inflammation, but IL-6–induced increases in synthesis by monocytes may also contribute.

Genetic Aspects

The gene for AMG is adjacent to the gene for pregnancy zone protein, on chromosome 12p12-13,[70] whereas the gene for its membrane receptor ("low-density lipoprotein–related protein") is at 12q13.1-13.2.[111] As noted previously, no individuals with complete genetic deficiency of AMG have been described. There are known genetic variants, however. Two reported mutations affect either the thiol ester or the bait region. The affected individuals were heterozygous, each having equal amounts of normal and mutant AMG. One patient heterozygous for a variant with either a deletion or a gene arrangement and reduced AMG levels developed chronic lung disease in childhood; reduced inhibition of pulmonary proteases may have played a role in pathogenesis, analogous to the pathophysiology of emphysema in AAT deficiency.

Laboratory Considerations

AMG and Hp together constitute most of the α_2-globulin zone on routine clinical serum electrophoresis. In the newborn period, and in in vivo hemolysis, AMG alone is the major contributor to this zone.

Although the two forms of AMG cannot be distinguished on routine electrophoresis, native AMG migrates slightly cathodal to AMG that has reacted with either proteases or nucleophilic substances that split the thiol ester bond. This characteristic can be used to determine the degree of inactivation that has occurred either in vitro or in vivo (e.g., in pancreatitis); monoclonal antibodies specific for the two forms can also be used in immunoassays for the same purpose. Using the latter assay, normal plasma contains 0.8% to 1.9% of AMG in the complexed form.[54]

AMG levels in urine may be measured to distinguish among causes of proteinuria or hematuria. Elevated levels are seen with intrarenal bleeding from vessel rupture during extracorporeal lithotripsy, and AMG-albumin ratios approximate serum ratios in postrenal bleeding.

Reference Intervals

The interim recommended reference interval for white adults is 1.3 to 3.0 g/L (130 to 300 mg/dL).[28] Levels are approximately twice this in children, with a maximum at 2 to 4 years of age; levels in women are 20% to 30% higher than in men after age 40.

Alpha$_1$-Fetoprotein

Alpha$_1$-fetoprotein (AFP) is a glycoprotein with a single polypeptide chain and approximately 4% carbohydrate. It has a molecular weight of approximately 70 kDa.

Biochemistry and Function

AFP is a major protein in fetal serum, synthesized by the fetal liver and to a lesser extent by the yolk sac and other fetal

organs. The maximum level in fetal serum is reached at the end of the first trimester, after which it decreases. The level at birth is approximately 1% of the earlier peak and then decreases with a half-time of about 3 days; after 18 months the level is less than 2 ng/mL. The level in maternal serum peaks at approximately week 30 of gestation. AFP is a fetal albumin analog. In addition, some isoforms bind and inactivate estrogen, presumably protecting the fetus from the high maternal levels of this hormone.

Clinical Significance

Determination of AFP levels in amniotic fluid or maternal serum is used for antenatal screening for certain birth defects and chromosomal abnormalities in the fetus (see Chapter 54). Elevated maternal serum AFP indicates the possibility of a neural tube or open abdominal wall defect in the fetus.[7] The levels may also be elevated with multiple fetuses, low birth weight, fetal demise, and incorrect estimation of gestational age. Trisomy 21 (Down syndrome) and trisomy 18 are associated with low maternal serum AFP levels.[42] AFP is also used as a marker for hepatocellular and germ cell carcinomas. For a discussion of the role of AFP as a tumor marker, see Chapter 23.

Reference Intervals

Newborn	<5 mg/L
>18 mo	<2 µg/L

Beta$_2$-Microglobulin

Beta$_2$-microglobulin (BMG) is a low molecular weight (11.8 kDa) protein found on the cell surfaces of all nucleated cells and shed into the blood, particularly by B lymphocytes and some tumor cells.

Biochemistry

BMG is the light or β-chain of the human leukocyte antigen and consists of a single polypeptide chain with one intrachain disulfide bridge; it does not contain carbohydrate. Its small size allows BMG to pass through the glomerular membrane, but normally less than 1% of the filtered BMG is excreted in the urine; the remainder is reabsorbed and catabolized in the proximal tubules of the kidneys. It has a plasma half-life of only 107 minutes.

Clinical Significance

High plasma levels occur in renal failure, inflammation, and neoplasms, especially those associated with B lymphocytes. BMG assay may be used to test renal tubular function, particularly in kidney transplant recipients in whom rejection of the allograft manifests as diminished tubular function (see Chapter 45). Serial assays of BMG are also useful to monitor B-cell tumors. In acute leukemia and lymphoma with central nervous system (CNS) involvement, the level of BMG is increased in CSF; and in Sjögren's syndrome with lymphoid infiltration of salivary glands, its level rises in saliva.

C-Reactive Protein

Tillet and Francis in 1930 described a substance that is present in the sera of acutely ill patients and that is able to bind the cell wall C-polysaccharide of *Streptococcus pneumoniae* and agglutinate the organisms. In 1941 the substance was shown to be a protein and given the name C-reactive protein (CRP).

Biochemistry

CRP consists of five identical, nonglycosylated polypeptide subunits noncovalently linked to form a disk-shaped cyclical polymer with a molecular weight of ~115 kDa. It contains little or no carbohydrate and is synthesized in the liver.

CRP binds not only the polysaccharides present in many bacteria, fungi, and protozoal parasites but—in the presence of free calcium ions—phosphorylcholine; phosphatidylcholines, such as lecithin; and polyanions, such as nucleic acids. In the absence of calcium ions, CRP also binds polycations, such as histones.

Function

CRP is important in the nonspecific host defense against inflammation, especially infection. In addition, it binds to tissue breakdown products (e.g., from inflammatory processes). The complexes activate the classical complement pathway starting at C1q (see next section), resulting in phagocytosis via C3b receptors. However, CRP complexes bind factor H, a complement inhibitory factor, greatly reducing the activation of late components (C5 to C9) and positive feedback via the alternative pathway (see Complement C3).[74] CRP is catabolized by opsonization, the process by which bacteria are altered in such a manner that they are more readily and more efficiently engulfed by phagocytes. However, whether CRP is catabolized by any other route is not clear. Similar proteins capable of Ca^{2+}-dependent binding to C-polysaccharide occur in fish and birds, and in mammals. Their appearance is similar to CRP on electron microscopy, and they have similar amino acid sequences. No genetic abnormalities have been reported for circulating CRP, although genetic deficiency and DNA variants have been suggested.

Clinical Significance

Acute Phase Response. CRP is one of the most sensitive of the APR with plasma levels rising up to 2000-fold after myocardial infarction, stress, trauma, infection, inflammation, surgery, or neoplastic proliferation. Levels are in general much higher in bacterial than viral infection, although levels greater than 100 mg/L (10 mg/dL) may be seen in uncomplicated influenza and infectious mononucleosis. The increase with inflammation occurs within 6 to 12 hours and peaks at about 48 hours. It is generally proportional to the degree of tissue damage. Because the

increase is nonspecific, however, it cannot be interpreted without other clinical information. Umbilical cord blood normally has low CRP concentrations (1 to 35 μg/dL), but in intrauterine (fetal) bacterial infection, levels may be as high as 26 mg/dL.

Determination of CRP is clinically useful for screening for organic disease; for assessing the activity of an inflammatory disease, such as rheumatoid arthritis; for detecting intercurrent infections in systemic lupus erythematosus (SLE), in leukemia, or after surgery (secondary rise in plasma level); for detecting rejection in renal allograft recipients; and for managing neonatal septicemia and meningitis, when collecting specimens for bacteriological investigations may be difficult.

For unknown reasons, the degree of CRP response varies in some diseases that are otherwise apparently similar. For example, the CRP response in SLE and ulcerative colitis, even when there are obvious signs and symptoms of inflammation, is slight in contrast to its frequently large response in rheumatoid arthritis and Crohn's disease.

To summarize, it is very important to remember that CRP levels greater than 5 to 10 mg/L are likely to be associated with clinically significant acute or chronic inflammatory disease (e.g., bacterial infection or malignancy), which should be identified and treated.

Risk of Cardiovascular Disease. Epidemiological studies have demonstrated that increased serum CRP concentrations are positively associated with risk of future coronary events, such as coronary artery disease, cerebrovascular disease, or peripheral arterial disease, and levels may be combined with cholesterol markers in estimating risk[89] (see Chapters 26 and 44). The use of CRP for these purposes requires the use of "high-sensitivity" CRP assays (hs-CRP) having detection limits less than 0.3 mg/L. However, some studies have shown no improvement in risk prediction by adding CRP.[108] It is likely that the increased levels reflect low-grade, chronic intimal inflammation rather than a direct role for CRP in atherogenesis.

Laboratory Considerations

Because CRP is normally present in plasma at a concentration of less than 5 mg/L (50 μg/dL), highly sensitive immunochemical methods are required for its quantification. Current assays include particle-enhanced immunoturbidimetry or nephelometry, immunofluorescence, and immunochemiluminescence. CRP migrates on cellulose acetate or agarose gel electrophoresis anywhere from the slow-γ to mid-β regions, depending upon the calcium ion content of the buffer.

Reference Interval

The reference interval for CRP in adults is $1 < 5$ mg/L (500 μg/dL).[28]

Ceruloplasmin

Ceruloplasmin (Cp) is an α_2-globulin that contains approximately 95% of the total copper found in serum. Each molecule of Cp contains six to eight copper atoms, most of which are tightly bound. The high content of copper ions gives Cp a beautiful blue color (L. *caeruleus* = blue). When Cp levels are greatly elevated, as in pregnancy, or the normal yellow pigments of plasma are decreased, as in active rheumatoid arthritis, plasma may have a green tint. Cp can also bind, and perhaps transport, other divalent cations, such as magnesium.

Biochemistry

Ceruloplasmin has a single polypeptide chain with 1046 amino acids and three glucosamine-linked oligosaccharide side chains, with a total carbohydrate content of 8% to 9.5%. The peptide chain and carbohydrate together result in a mean molecular mass of 132 kDa. Cp in serum shows significant size and charge heterogeneity because of differences in glycosylation, the number of copper atoms present, peptide chain variations secondary to alternative DNA splicing, and polymerization. In addition, it is very susceptible to proteolysis, both in vivo and in vitro, by many proteases, including trypsin, plasmin, leukocyte elastase, and a plasma metalloproteinase. This lability accounts for earlier reports of more than one peptide chain.

Ceruloplasmin is synthesized primarily by the hepatic parenchymal cells, with small amounts synthesized by macrophages and lymphocytes. The peptide chain is formed first, then copper is added from an intracellular ATPase (absent in Wilson's disease; see later in this chapter); Cu^+-glutathione complexes may be involved in the transfer. The CHO side chains are subsequently added in the endoplasmic reticulum. Copper appears to be essential for the normal folding of the polypeptide chain and possibly for normal CHO side chain attachment. However, apoCp is synthesized even in the absence of copper or the ATPase; most is degraded intracellularly, but moderate amounts are released into the circulation, where apoCp has a very short half-life.

Sialic acid is slowly removed from circulating Cp by tissue and plasma neuraminidases, resulting in exposure of the penterminal galactose residue on the carbohydrate side chains. Once a critical number of galactose residues are exposed, the protein is rapidly removed by galactose receptors of the hepatic parenchymal cells and catabolized. Markedly increased catabolism by this route may result in deposition of excessive copper in the liver. The normal plasma half-life of intact, holoCp (copper replete) is 4 to 5 days, whereas that of apoCp is a few hours and that of desialylated Cp a few minutes.

Function

The primary physiological role of Cp involves plasma redox reactions. It can function either as an oxidant or an antioxidant depending on other factors, such as the presence of free ferric ions and ferritin binding sites. Acting as a ferroxidase, Cp is vitally important in regulating the ionic state of iron in particular, oxidizing Fe^{2+} to Fe^{3+} (Figure 20-4). It thus permits the incorporation of iron into transferrin without the formation of toxic iron products. Under physiological

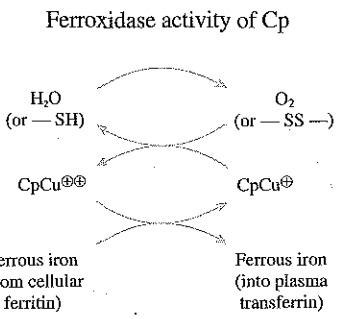

Figure 20-4 Proposed function of ceruloplasmin copper ($CpCu^{2+}$) as a proton (hydrogen ion) recipient from cellular ferrous iron. The resulting oxidation of Fe^{2+} to the ferric state permits its binding and transport by plasma transferrin. $CpCu^{+}$ is oxidized (regenerated to $CpCu^{2+}$) by reaction with oxygen, oxidized thiol groups, or other oxidizing substances. *(Modified from Johnson AM. Ceruloplasmin. In: Ritchie RF, Navolotskaia O, editors. Serum proteins in clinical medicine. Vol. I: Laboratory section. Scarborough, ME: Foundation for Blood Research, 1996:13.01-13.03.)*

conditions, Cp is also important in the control of membrane lipid oxidation—probably by direct oxidation of cations—thus preventing their catalysis of lipid peroxidation. At the same time, in the presence of superoxide (e.g., in inflamed vascular endothelium), Cp is a major contributor to low-density lipoprotein (LDL) oxidation.[37] Its role in oxidation of 6-hydroxydopamine may be important in brain function, perhaps explaining the early neurological symptoms seen in severe genetic deficiency.[36]

Cp may transport small amounts of copper to tissue, which have separate membrane receptors for Cp- and albumin-bound copper. The importance of Cp in transport is debated, however, because turnover of Cp copper is very slow and individuals with genetic deficiency of Cp have no problems related to copper transport (see later in this chapter). Albumin and transcuprein are the major copper transport proteins, especially following absorption from the intestinal tract.

Clinical Significance

Cp is most often measured as a screening test for Wilson's disease. Several other factors, including diet, hormone levels, and other genetic disorders, also influence plasma levels. Immunochemical assays may not distinguish between the active, copper-replete holoCp and apoCp, which is released into the circulation in most of the disorders associated with low total Cp levels. Functional assays might therefore be helpful in clinical circumstances, but they are more difficult to perform and less specific.

Increased Plasma Levels. Cp levels are increased as a result of primary and secondary elevations.

Primary (Genetic) Elevation. EL mice have a Cp gene duplication that results in elevated Cp levels by both immunochemical and copper oxidase methods of assay.[39] Affected mice have an epileptic disorder similar to human complex partial seizures, possibly because of Cp-induced neuronal membrane depolarization. Conversely, rats deficient in copper and Cp have diminished auditory startle responses.[85] There are no published reports of Cp levels in human patients with seizure disorders.

Secondary Elevations. Synthesis of Cp is increased modestly in the APR. The increase occurs relatively slowly, peaking at 4 to 20 days after a single, acute insult. Synthesis is stimulated markedly by estrogens, with moderate increases seen in women taking estrogen-containing medications and larger increases during pregnancy.

Decreased Plasma Levels. Cp levels are decreased as a result of various primary and secondary deficiencies.

Primary (Genetic) Deficiency. Inherited deficiency of Cp has been reported in several families. Clinical findings in homozygous individuals include blepharospasm, retinal degeneration, diabetes mellitus, dementia, and extrapyramidal tract disorders. No patients have shown excessive tissue copper, but all have had increased tissue iron stores and decreased serum iron. This argues strongly for the hypothesis that the primary physiological role of Cp is for maintaining normal iron transport and metabolism. Serum iron levels increase for several hours following infusion of fresh frozen plasma. The clinical picture is similar to that of hereditary hemochromatosis, although CNS effects are greater and no patients to date have shown the arthritis and cardiomyopathy commonly seen in hereditary hemochromatosis.[127,128]

Secondary Deficiency. Low plasma Cp levels caused by a lack of incorporation of Cu^{2+} into the molecule during synthesis are much more common than primary deficiency. Secondary deficiency may be due to dietary Cu^{2+} insufficiency (including malabsorption), inability to release Cu^{2+} from the gastrointestinal epithelium into the circulation, or inability to insert Cu^{2+} into the developing Cp molecule. In all cases, apoCp (noncopper containing) is still synthesized by the hepatic parenchymal cells. However, as mentioned previously, most apoCp is catabolized intracellularly before release into the plasma, and plasma apoCp has a much shorter half-life than does holoCp. Levels may also be low in blood loss or in gastrointestinal or renal protein-losing syndromes.

Dietary Cp deficiency is due to nutritional copper deficiency, with secondarily low levels of Cp, and is associated with neutropenia, thrombocytopenia, low serum iron, and hypochromic, normocytic, or macrocytic anemia unresponsive to iron therapy. The deficiency may be due to inadequate dietary intake, long-term parenteral nutrition without copper supplementation, malabsorption of any cause, penicillamine therapy, or combinations of these. Therapy includes dietary change or copper supplementation, plus treatment of the primary cause of malabsorption if present.

Menkes' disease is an X-linked inherited disorder in which dietary copper is absorbed from the gastrointestinal tract but cannot be transported to the vascular space because of the genetic absence of an intracellular ATPase.[113] Hence, copper

is not available to the liver for incorporation into Cp. Affected infants manifest abnormal hair (sparse, brittle, and kinky), growth restriction, and progressive neurological degeneration, with death occurring during the first few years of life if untreated. Subcutaneous injections of copper histidine partially reverse the deleterious effects if started early in life; some residual Menkes' ATPase activity (i.e., incomplete deficiency) may be necessary for this response, however. Patients with deficient gastrointestinal *and* blood-brain barrier transport of copper have also been described; the neurological symptoms in these patients are not reversed by copper therapy.[38] The gene for Menkes' disease is on chromosome Xq13.3-21.2.

Wilson's disease, or hepatolenticular degeneration, differs from dietary deficiency and Menkes' disease in that body copper is markedly increased and is deposited in tissue, including the hepatic parenchymal cells, the brain, and the periphery of the iris (resulting in the characteristic Kayser-Fleischer rings). Copper is absorbed and transported to the liver, but the absence of a hepatocellular P type of ATPase (similar to that missing in Menkes' disease) prevents incorporation of copper into Cp. The gene for this ATPase is on chromosome 13q14.3.[8]

Symptoms in patients with Wilson's disease usually begin in the second or third decade of life, but may be earlier or later. However, mutations that completely destroy gene function may be associated with onset of liver disease as early as 3 years of age. The initial clinical presentation may be hepatic, with presentation similar to acute hepatitis or to chronic active hepatitis; neurological (e.g., clumsiness, dysarthria, ataxia, and tremors); renal (renal tubular acidosis with aminoaciduria); or, less commonly, hematological, with hemolysis secondary to acute release of free copper from tissue and subsequent oxidation of erythrocyte membranes. The hepatic, and possibly CNS, damage may also be secondary to copper-induced oxidative damage to mitochondrial membranes.[99] Hepatic levels of Cp messenger ribonucleic acid (mRNA) are reduced in patients with Wilson's disease, probably secondary to inhibition of transcription by increased intracellular levels of apoCp.[8]

Most patients with Wilson's disease have plasma Cp levels below 0.1 g/L (10 mg/dL), and the mean Cp level in these patients is ~50 mg/L (5 mg/dL). However, some—particularly those with inflammatory diseases or pregnancy—may have low normal levels. Cp levels are low in 10% to 12% of obligate heterozygotes for the Wilson's disease gene and normal in the rest, possibly because of different mutations. Low Cp levels are also seen in other disorders, as noted earlier. Clinical diagnosis of Wilson's disease therefore requires presence of the classical signs of the disease, documentation of copper excess, or both. Slit-lamp examination for Kayser-Fleischer rings, assays of urine copper, and, if these are not diagnostic, liver biopsy for quantitative copper assay may be required for definitive diagnosis. DNA analysis also permits definitive diagnosis in most cases, even in the absence of clinical abnormalities.

Genetic Aspects

There are several genetic variants or isotypes of Cp, but none of these, except for genetic deficiency (see previous discussion in this chapter), has known clinical significance. The most prevalent isotypes are CpA, CpB, and CpC, which are detectable by electrophoresis followed by either immunofixation or functional staining; CpB is the common, or "wild," isotype. The gene encoding Cp is on chromosome 3q25.[126]

Laboratory Considerations

Because of its lability, Cp may lose some or all of its copper either spontaneously or secondary to oxidation during in vitro storage of serum. In addition, fragmentation of the peptide chain by enzymes in normal serum and leukocytes may result in altered reactivity with antibodies. This lability may create problems with calibrators, controls, and quality control materials and with patient samples. Depending on the degree of degradation and the assay method, apparent levels may increase or decrease. Serum or plasma from patient samples should be separated as soon as possible after collection and either assayed promptly or stored under proper conditions (up to 3 days at 4 °C; longer storage at −70 °C).

Ceruloplasmin can be assayed immunochemically or functionally (copper oxidase activity). The latter assays measure only native, copper-containing Cp, whereas the former measure both the intact molecule and, to varying degrees, apoCp and proteolytic fragments.

Reference Intervals

Ceruloplasmin is undetectable before 20 weeks of gestation. Plasma levels then gradually rise by term to 25% to 40% of the normal adult level and by 6 months of age to nearly adult levels (Table 20-6). Levels at birth do not correlate with birth

TABLE 20-6 Plasma Ceruloplasmin Reference Intervals*

Age	Reference Interval (mg/L)	
Cord (term)	50-330	
Birth-4 mo	150-560	
5-6 mo	260-830	
7-36 mo	310-900	
4-12 yr	250-450	
	Male	**Female**
13-19 yr	150-370	220-500
Adults	220-400	250-600 (No OC)
		270-660 (OC; estrogens)
		300-1200 (Pregnant†)

OC, Oral contraceptives.
*Converted to CRM 470 values from multiple references.
†Second and third trimesters; levels increase with increasing gestational age.

weight, and copper supplementation does not increase levels in the first few weeks of life; the low levels are probably secondary to immaturity of the fetal and neonatal liver. The reference interval for neonates is 0.19 to 0.67 g/L.

Serum Cp levels reach a maximum at 2 or 3 years of age, then fall slowly until the adolescent years, when adult levels are reached. Levels are higher in women during their menstrual years (and longer if estrogen replacement therapy is used). There appears to be a genetic influence on synthetic rates; levels within families vary less than do those among families. The recommended interim reference interval for all adults of both sexes, based on CRM 470, is 0.2 to 0.6 g/L (20 to 60 mg/dL).[28]

Haptoglobin

Hp is an α_2-glycoprotein that irreversibly binds hemoglobin (G. *haptein* = to bind).

Biochemistry

Haptoglobin is synthesized by the hepatic parenchymal cells and is composed of four peptide chains linked by disulfide bonds into two pairs, an $(\alpha\beta)_2$ configuration similar to that of hemoglobin. The two chains are synthesized together and then separated by cleavage at an arginine residue. The Hp α-chain exists in two common genetically determined molecular forms, monomeric (α^1) and partially dimeric (α^2; probably the result of incomplete genetic crossover). In addition, one variant has partial triplication. The monomeric Hp α^1-chain has 83 amino acid residues and is partly homologous to kringle 5 of plasminogen; the β-chain, with 245 amino acid residues plus carbohydrate side chains, is related to the serine proteases. The molecular mass of the Hp 1-1 isotype, $(\alpha^1\beta)_2$, is approximately 85 kDa.

During extracellular hemolysis, hemoglobin is released from the erythrocytes, and the hemoglobin tetramers separate into αβ dimers at the low local concentration of hemoglobin. The free dimers bind almost immediately to free Hp. Each Hp monomer can bind up to two hemoglobin αβ dimers, the equivalent to one intact hemoglobin molecule; the Hp β-chain binds to hemoglobin α-chains. Hp-hemoglobin complexes are large enough to prevent, or greatly reduce, renal loss of hemoglobin and its iron. The complexes are very rapidly removed by the hepatic Kupffer cells and by macrophages, via CD163 receptors, where the proteins are degraded and the iron and amino acids are reused. Hp is therefore a "suicidal" protein and not strictly a carrier or transport protein. The normal plasma half-life of Hp is approximately 5.5 days.

Function

The primary functions of Hp were initially thought to be the preservation of iron and the prevention of possible damage to the renal tubules by excreted hemoglobin. However, Hp-hemoglobin complexes and free Hp itself also play significant roles in the control of local inflammatory processes:

1. The Hp-hemoglobin complex is a potent peroxidase, capable of hydrolyzing peroxides released during phagocytosis and killing by polymorphonuclear leukocytes at sites of inflammation; complexing of hemoglobin by Hp prevents lipid peroxidation.
2. Hp inhibits cathepsin B released by the phagocytes and binds to and modulates proliferation or activity of lymphocytes, monocytes, and granulocytes, possibly by binding to integrins.
3. Hp is a natural bacteriostatic agent in infection with iron-requiring bacteria, such as *Escherichia coli,* probably by preventing the use of hemoglobin iron by these organisms.
4. Hp synthesis is stimulated by inflammation but not by hemolysis (and depletion of Hp), suggesting teleologically that the role of Hp in local inflammation may be its primary role and function.

Other proposed functions for Hp or the Hp-hemoglobin complex include inhibition of nitric oxide and prostaglandin synthesis, angiogenesis, and control of lymphocyte and neutrophil function. All of these may be relevant to the control of inflammation.

Clinical Significance

Under normal circumstances, approximately 1% of circulating red blood cells are removed from the circulation or destroyed intravascularly each day. An increase to only 2% destruction per day will completely deplete plasma Hp in the absence of a stimulus to production, such as acute inflammation or corticosteroid therapy.

Once Hp is depleted, further hemolysis may be associated with other phenomena. First, hemoglobin may be oxidized to methemoglobin, followed by dissociation of metheme from globin. Metheme is insoluble but can bind to either hemopexin (high affinity) or albumin (low affinity), keeping it in solution. Hemopexin-heme complexes are removed by the reticuloendothelial system (as with Hp-hemoglobin complexes, but more slowly), with subsequent intracellular catabolism of the complex and a decrease in the hemopexin level in plasma.[124] Hemopexin synthesis is relatively unaffected by other factors (such as estrogen) that decrease Hp synthesis, so low values usually reflect fairly severe or prolonged hemolysis. Like Hp, it is a positive (but weak) APR. Disorders with both ineffective hematopoiesis and peripheral or splenic lysis of abnormal cells, including some hemoglobinopathies (e.g., sickle cell disease), are associated with chronic depletion of Hp and hemopexin.[124] Albumin also binds heme, but with lower affinity than hemopexin, to form methemalbumin. Because of the higher affinities of hemoglobin for Hp and of hemopexin for heme, methemalbumin may not be seen until Hp and hemopexin are depleted.

Alternatively, free αβ dimers may pass through the glomerular filter into the urine. The dimers are normally reabsorbed and catabolized by the proximal tubules and catabolized, with the iron incorporated into cellular ferritin and hemosiderin. Iron may reach toxic levels in the tubular

TABLE 20-7 Correlation of Haptoglobin and α_1-Acid Glycoprotein (Orosomucoid) Changes With Hormonal Effects and Diseases

Haptoglobin	α_1-Acid Glycoprotein	Usual Interpretation
N	*N*	Normal
↑	↑	Acute phase response; corticosteroid or androgen effect
↓	*N*	Hemolysis; hepatocellular disease (with increased red blood cell turnover)
↓	↑	Hemolysis plus acute phase response, corticosteroid therapy, or both
↓	↓	Estrogen effect; hepatocellular disease

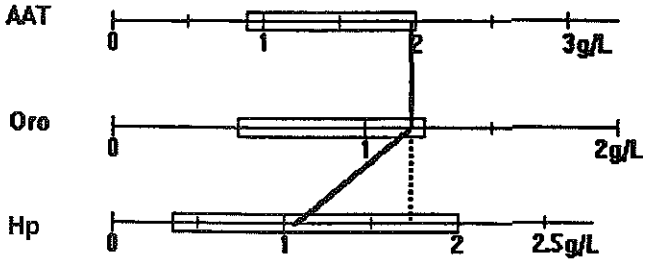

Figure 20-5 Protein profile of α_1-antitrypsin (AAT), α_1-acid glycoprotein (Oro), and haptoglobin (Hp) in a hypothetical individual with in vivo hemolysis. The jagged vertical line connects the concentration values for the proteins.

cells, which may slough into the excreted urine. If the ability of the proximal tubules to reabsorb is exceeded, or if significant damage has occurred, free hemoglobin is seen in the excreted urine. Hemoglobinuria may also be secondary to renal or postrenal bleeding, which must be excluded in the evaluation of hemoglobinuria.

Thus Hp depletion is usually the most sensitive laboratory indicator of hemolysis, followed by hemopexin depletion and finally by the presence of methemalbuminemia, hemoglobinuria, or both. However, Hp levels are influenced by several other factors, as discussed later. It is recommended that Hp always be assayed in association with AAG (orosomucoid), because the other factors—with the exception of protein-losing syndromes—influence the levels of both proteins in parallel (Table 20-7, Figure 20-5). If a patient has a normal Hp level but high AAG level, the possibility of hemolysis plus either corticosteroid therapy or an APR must be considered.

As a result of its role in hemoglobin metabolism, Hp assays are used primarily to screen for, or to follow the course of, hemolytic disorders.

Increased Plasma Levels. Increased levels of Hp are seen in the APR and protein-losing syndromes and associated with corticosteroid effects.

Acute Phase Response. Hp synthesis is increased in the presence of acute inflammatory processes, tissue necrosis, or malignancy. Increased plasma levels are seen approximately 4 to 6 days after the initiation of these processes and take about 2 weeks to fall to normal after the removal of the stimulating factors. Stimulation of synthesis is mediated by cytokines, particularly IL-6.

Protein-Losing Syndromes (in Association with Hp 2-1 or 2-2 Phenotypes). Most protein-losing syndromes, such as the nephrotic syndrome, are associated with sieving loss of plasma proteins, with excretion inversely proportional to the effective diameter of the protein (Stokes radius). There is a concomitant, compensatory increase in synthesis of most if not all proteins synthesized in the liver, including Hp. Hp 1-1 is relatively small and is lost in approximately the same proportion as albumin. However, the 2-1 and 2-2 variants are large; these are retained, and elevated concentrations are usually seen unless hemolysis is also present.

Corticosteroid Effects. Glucocorticoids, such as cortisol (endogenous) and dexamethasone (exogenous), and androgens are associated with increased synthesis of Hp and secondarily elevated plasma levels. Dexamethasone acts, at least in vitro, by enhancing the response of synthesis to interleukins rather than by a direct effect on synthesis.

Decreased Plasma Levels. Decreased levels of Hp are seen with genetic deficiency, hemolytic disease, ineffective erythropoiesis, estrogens, and hepatocellular disease and in neonates.

Genetic Deficiency. Genetic absence (anhaptoglobinemia, or *Hp0*) and hypohaptoglobinemia have been reported in many populations, especially in those of African extraction. However, most reports have been in populations with high rates of hemolytic disease, either genetic (e.g., hemoglobinopathies and glucose-6-phosphatase deficiency) or acquired (e.g., malaria). True *Hp0* (total deficiency) is rare in most if not all populations. More commonly, genetic hypohaptoglobinemia is associated with very low, but phenotypable, levels of Hp probably secondary to altered control of gene transcription rather than a defect in the *Hp* gene itself.

Hemolytic Disease and Ineffective Erythropoiesis. As discussed previously, Hp levels are a sensitive indicator of in vivo hemolysis, as long as other causes of decreased levels are excluded. Splenomegaly and ineffective hematopoiesis are also associated with decreased levels. The latter, with increased hemolysis of red cells and their precursors in the bone marrow space, is seen in megaloblastic anemias

(vitamin B_{12} or folate deficiency) and in many hemoglobinopathies.

Estrogens. Either endogenous or exogenous estrogens (e.g., in late pregnancy and in oral contraceptive therapy) result in decreased Hp synthesis and plasma levels.

Hepatocellular Disease. Most forms of acute or chronic hepatocellular disease, including acute viral hepatitis and cirrhosis with jaundice, are associated with decreased levels of Hp, possibly caused in part by altered estrogen metabolism. Increased red cell breakdown secondary to erythrocyte membrane lipid alterations may also play a role, although this has never been documented with turnover studies. In contrast, biliary obstruction is also associated with significant lipid alterations but with increased Hp levels, in the absence of severe hepatocellular disease.

Newborn Period. Hp is absent or present in very low concentration in most newborn infants as a result of hepatic immaturity. In addition, hemopexin levels in newborns are on average one fifth of adult levels. The absence of Hp and hemopexin in the normal fetus may prevent in utero stimulation of the hepatic excretory mechanisms for bilirubin (fetal bilirubin is normally excreted by the placenta and the maternal liver).

Genetic Aspects

The gene encoding Hp is on chromosome 16 at band q22. Both chains are polymorphic, but the α-chain accounts for the commonly recognized isotypes. As mentioned previously, the α-chains exist in different genetically determined sizes, with α^1 the basic monomer. The two common α^1 variants, α^{1F} and α^{1S}, differ only in one amino acid at position 54 (lysine in α^{1F} and glutamic acid in α^{1S}). Of the two, α^{1S} is the more frequent.

The α^2 variants are products of partial gene duplication, probably from unequal crossing over,[98] and are nearly twice the length of the α^1 variants (142 versus 83 amino acid residues). The three possible α^2 products (α^{2FF}, α^{2FS}, and α^{2SS}) have all been described, with α^{2FS} the most common in white populations. Homozygosity for the α^1 alleles results in the phenotype Hp 1-1, with a molecular mass of 85 kDa. Heterozygosity for α^2 and α^1 results in Hp 2-1 (molecular mass of the monomer = 120 kDa), and homozygosity for α^2 in Hp 2-2 (160 kDa). The latter two phenotypes polymerize to form a series of polymers, with molecular masses up to at least 1000 kDa; the Hp 2-2 polymers differ by increments of one $\alpha^2\beta$ dimer (~57.3 kDa). As a result, phenotyping can be performed fairly easily by sieving electrophoresis in starch or polyacrylamide gels (Figure 20-6), usually as Hp-hemoglobin complexes, which can be detected by their peroxidase characteristics. Alternatively, immunofixation can be used after electrophoretic separation. The α-chain subtypes (α^{1S}, α^{1F}, α^{2FF}, α^{2FS}, and α^{2SS}) are detected by isoelectric focusing of reduced, neuraminidase-treated serum or plasma, followed by blotting onto nitrocellulose membranes and immunoperoxidase staining.

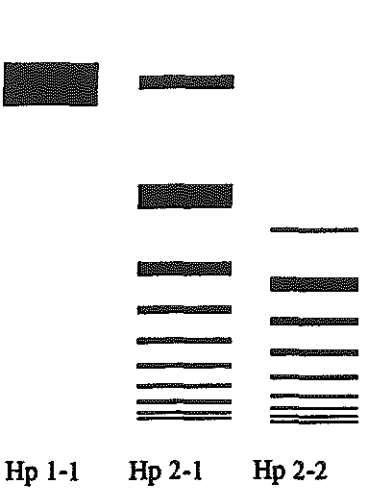

Figure 20-6 The common phenotypes of haptoglobin, as shown by sieving gel electrophoresis of haptoglobin-hemoglobin complexes.

Less common variants include Hp Johnson, in which there is triplication of a portion of the α-chain, and Hp 2-1Mod, a 2-1 phenotype in which there is greatly reduced production in α^2-chains. As mentioned previously, true genetic anhaptoglobinemia (Hp0) is rare; individuals with ring chromosome 16 have terminal deletions of the Hp gene and therefore do have true deficiency. Very low levels on a genetic basis are more commonly caused by decreased transcription, with resulting hypohaptoglobinemia.

The Hp 2-2 phenotype is associated with higher serum iron, ferritin, and transferrin saturation, perhaps because of its preferential uptake by CD163 receptors.[30] Other possible clinical associations of the Hp polymorphism have been reviewed by Langlois and Delanghe.[63]

Laboratory Considerations

Hp and AMG together with Hb-hemoglobin complexes (usually from in vitro hemolysis) migrate more cathodally (Figure 20-6). Traditionally, Hp was measured by assaying peroxidase activity after mixing serum with an excess of free hemoglobin, the so-called hemoglobin binding capacity (BC). On average, [Hp] = [Hp BC] × 1.5; approximately 1 mg hemoglobin is bound by 1.5 mg Hp, depending on the phenotype.

Immunochemical methods are also used for clinical assays because they are rapid and easily automated. Because of the differences in molecular size and corresponding diffusion rates, gel diffusion techniques, such as radial immunodiffusion (RID) require correction for phenotype and are therefore time consuming and inconvenient. Immunoassays in solution, such as nephelometry and turbidimetry, are influenced slightly by size as well, but the differences are relatively insignificant.

Reference Intervals

The recommended interim reference interval for Hp in serum for adults is 0.3 to 2.0 g/L (30 to 200 mg/dL).[28] As noted previously, levels are low to absent in the neonatal period and are low in women who are either pregnant or on exogenous estrogen therapy, including oral contraceptives. For children the reference interval is approximately 0.2 to 1.6 g/L.

Transferrin

Transferrin (originally named *siderophilin*) is the principal plasma transport protein for iron (Fe^{3+}); see Chapter 31.

Biochemistry

Transferrin (Tf) has a molecular weight of approximately 79.6 kDa, including 5.5% carbohydrate. It is a single polypeptide chain, with the carbohydrate moieties in the C-terminal domain and two homologous domains, each containing an Fe^{3+} binding site.[110] It is synthesized almost exclusively in the liver, with lesser amounts in the choroid plexus of the brain. Plasma levels are regulated primarily by availability of iron; in iron deficiency, plasma Tf levels rise and, on successful treatment with iron, return to normal. Tf has a half-life of approximately 8 to 10 days. The primary route of catabolism is not known, but some Tf is lost from the body in exfoliated intestinal mucosal cells and other cells. As with albumin, about half of Tf exists outside the vascular compartment in body fluids, such as lymph and CSF.

Tf reversibly binds numerous polycations—iron, copper, zinc, cobalt, and calcium—although only iron appears to have physiological significance. One molecule of Tf binds two ferric ions and an associated anion, usually bicarbonate. There are two binding sites for iron with different affinities; both are strong at physiological pH but decrease with decreasing pH. The iron-Tf complex has an absorbance maximum at 470 nm. Cp is necessary for the oxidation of Fe^{2+} to Fe^{3+} as a preliminary step for binding of Fe^{3+} to Tf.

Function

Iron metabolism is discussed in Chapter 31; thus only a brief discussion of the role of Tf is presented here. Apotransferrin binds iron absorbed from the intestine or released from catabolism of hemoglobin. The iron is then transported to storage sites, such as the liver and reticuloendothelial system, and to sites of synthesis of iron-containing compounds, especially the erythropoietic tissue (for hemoglobin synthesis). However, virtually every cell type has surface receptors for Tf.[64] The receptors have a much higher affinity for Tf-Fe^{3+} than for apotransferrin (Tf without iron). After binding, the Tf-Fe^{+3}-receptor complex is internalized into a caltherin-coated endosome that lowers the internal pH, resulting in release of iron from Tf. The free ferric iron, which is cytotoxic, is reduced and incorporated into ferritin and hemosiderin, for eventual synthesis of compounds, such as hemoglobin, myoglobin, and cytochromes. The receptor-apoTf complex is recycled to the cell surface where the apoTf is released and recycled, making the receptor available again for binding.

Clinical Significance

Increased Plasma Levels. Evaluation of plasma Tf levels is useful in the differential diagnosis of hypochromic microcytic anemia and for monitoring treatment. In iron deficiency, Tf is increased, but the protein is less saturated with iron. On the other hand, if the anemia is due to a failure to incorporate iron into erythrocytes (e.g., with chronic inflammatory disease), the Tf level may be normal or low, but the protein is normally saturated with iron. In iron overload (e.g., hereditary hemochromatosis), Tf concentration is normal, but saturation (normally 30% to 38%) exceeds 55% and may be as great as 100%. Assays of soluble transferrin receptor (sTfR) are useful in differentiating the various causes of microcytic anemia; if tissue iron deficiency is present, the affected cells increase their synthesis of transferrin receptors. Shedding of partial molecules into plasma, in direct proportion to the amount of receptor, is reflected by increased levels of sTfR. Thus levels are high in iron deficiency but normal in other disorders associated with microcytic anemia (e.g., partial α-thalassemia and inflammation). Although assays for sTfR are available, international standardization is needed.

High levels of Tf are also seen in pregnancy and during estrogen administration.

Decreased Plasma Levels. Transferrin is a negative APR; the most common cause of low levels is inflammation or malignancy. Decreased synthesis is seen with chronic liver disease and malnutrition (see Chapter 47). Protein loss, as in the nephrotic syndrome or protein-losing enteropathies, also results in low levels. In hereditary atransferrinemia, a very low level of Tf is accompanied by iron overload but severe hypochromic anemia resistant to iron therapy.

Carbohydrate-Deficient Transferrin (CDT). The glycosylation of transferrin (and of other glycoproteins) may be decreased or absent in certain circumstances. Congenital disorders of glycosylation, or the carbohydrate-deficient glycoprotein syndromes, are increasingly recognized in patients; they may be associated with defects of any of at least 9 genes and result in varying multisystem dysfunction, usually with brain involvement.[53]

CDT is also assayed extensively, especially in Europe, for detection of alcohol abuse. Other proteins, such as α_1-acid glycoprotein, are carbohydrate deficient in this case as well. The "gold standard" for assessment is HPLC, although both capillary electrophoresis and immunoassays are more commonly used in clinical settings. Immunoassays in particular are poorly standardized, both qualitatively and quantitatively; positive tests should be confirmed by an alternative method.[4] Genetic variants of Tf may also complicate interpretation of results.

Genetic Aspects

The gene coding for Tf is on chromosome 3q21-25. At least 22 genetic variants of Tf have been identified (pI 5.5-5.9), with heterozygosity present in up to 25% of some populations. The wild type is Tf C; the most common anodal and cathodal variants are Tf B and Tf C, respectively. The variants all bind iron and have no biological significance except for the rare congenital defect, atransferrinemia. However, they may be misinterpreted as M-components or as CDT.

Laboratory Considerations

Because of the convenience of simultaneous measurement of serum iron and total iron binding capacity (TIBC) and the desirability of knowing percent saturation of Tf (see Chapter 31), Tf is sometimes estimated indirectly from the TIBC value by the following equation:

$$\text{Tf, mg/dL} = 0.70 \times \text{TIBC, } \mu\text{g/dL}$$

or

$$\text{TIBC} = 1.43 \times \text{Tf}$$

This procedure overestimates the Tf concentration by 16% to 20% because it assumes that all plasma iron is bound to Tf. When Tf is more than half saturated (e.g., in hereditary hemochromatosis), some of the iron is bound to other plasma proteins including albumin.

Transferrin is commonly assayed by immunochemical methods, including immunoturbidimetry and immunonephelometry. It migrates in the β_1 region on routine serum electrophoresis; as noted previously, genetic variants may cause problems in interpretation of these patterns.

Reference Intervals

Serum reference intervals based on CRM 470[28] are as follows:

	g/L	mg/dL
Newborn	1.17-2.50	117-250
Adults (20-60 yr)	2.0-3.6	200-360
>60 yr	1.6-3.4	160-340

Transthyretin (Prealbumin) and Retinol-Binding Protein

Transthyretin (prealbumin) and retinol-binding protein (RBP) are transport proteins that migrate together as a 1:1 molecular complex. Transthyretin was originally named prealbumin because of its electrophoretic mobility; it was renamed in 1981 to reflect its binding and transport of both thyroid hormones (thyroxine and triiodothyronine) and RBP.

Biochemistry and Function

Transthyretin (TTR) is a nonglycosylated protein (MW 34.98 kDa) composed of four identical subunits, noncovalently bound to form a hollow core containing the T_3- and T_4-binding sites. It binds and transports approximately 10% of both hormones, with T_3 with higher affinity. (Thyroxine-binding globulin transports approximately 70%, and albumin binds the "overflow" with low affinity.) Because of negative cooperativity, TTR binding of the first hormone molecule decreases the binding affinity of the second, so only one site is normally occupied. TTR is synthesized in the liver and to a lesser extent in the choroid plexus of the CNS.[95] Its synthesis is stimulated by glucocorticosteroid hormones, androgens, and many nonsteroidal antiinflammatory drugs (NSAIDs, including aspirin).

Retinol-binding protein is a small (21 kDa), monomeric transport protein for all *trans* retinol, the physiologically active, alcoholic form of vitamin A.[100] It is synthesized in the liver. Zinc is required for synthesis, and retinol is required for its transportation by the Golgi apparatus.[91] When circulating in the plasma, RBP is in a 1:1 complex with transthyretin, preventing RBP from being filtered by the renal glomeruli and stabilizing the binding of retinol, reducing its release to nontarget cells. Uptake of retinol by target cells is followed by dissociation of the transthyretin-RBP complex and clearance of apoRBP (RBP without retinol) from the circulation by the kidneys. It is reabsorbed by the proximal renal tubular cells and catabolized; the amino acids are then reused.

Clinical Significance

If vitamin A intake is adequate and renal function is normal, levels of TTR and RBP tend to rise and fall synchronistically.

Increased Plasma Levels. Serum RBP increases in chronic renal disease, including diabetic nephropathy.[84] Levels are increased with corticosteroid or NSAID therapy and in Hodgkin's disease.

Decreased Plasma Levels. Decreased levels of RBP are seen primarily with liver disease, protein malnutrition, and the APR. Zinc deficiency is characterized by low serum levels of both RBP and vitamin A.

Transthyretin levels are often used as an indicator of protein status because of its relatively short half-life, a high tryptophan content, a high proportion of essential-to-nonessential amino acids, and small pool size. However, it is a negative APR. Levels fall in inflammation and malignancy and in cirrhosis of the liver and protein-losing diseases of the gut or kidneys. Therefore a sensitive acute phase reactant, such as CRP, should always be assayed along with TTR if levels are to be used to estimate nutritional status. History and physical examination are also important aspects of such evaluations.[55]

Genetic Aspects

The gene coding for TTR is on chromosome 18q. More than 50 genetic variants have been described, a few affecting hormone binding. The substitution of threonine for alanine at codon 109 increases the affinity of transthyretin for thyroxine and is associated with euthyroid *hyper*thyroxinemia. Euthyroid *hypo*thyroxinemia associated with genetic

deficiency of thyroxine-binding globulin (TBG) is most commonly seen in males; the gene for TBG is on the X chromosome.

Most TTR variants are associated with extracellular deposition of amyloid fibrils in various tissue. These autosomal dominant hereditary amyloidoses include amyloidotic cardiomyopathy, familial amyloidotic polyneuropathy, and senile systemic amyloidosis. There is phenotypic variability (e.g., variable age of onset), suggesting that other factors may influence pathogenesis of the diseases.

The RBP gene is on chromosome 10q.

Laboratory Considerations

TTR migrates anodal to albumin on routine serum electrophoresis; the presence of a TTR band is considered one marker of good quality electrophoresis. However, levels can be only roughly semiquantified from the intensity of the band. RBP dissociates during electrophoresis and migrates anodal to transferrin, but the band is usually too faint to see. Either protein can be quantified by routine immunochemical methods.

Reference Intervals

The adult reference interval for RBP is 3.0 to 6.0 mg/dL. The RBP level at birth is 1.1 to 3.4 mg/dL and at 6 months increases to 1.8 to 5.0 mg/dL.

The adult reference interval for transthyretin, based on CRM 470, is 20 to 40 mg/dL (0.2 to 0.4 g/L).[28] Levels in healthy neonates are approximately half those found in adults, then increase into puberty, with a larger increase in boys than girls, and decrease in both sexes after age 50.[49]

Other Proteinase Inhibitors

Plasma and other body fluids contain a large number of other proteinase inhibitors in addition to AAT and AMG. A few of the more important ones are presented in Table 20-8.

Complement Proteins

The complement system consists of at least 20 proteins, which can be divided into five groups by function:

1. The *classical pathway,* which includes C1, C4, C2, and C3 (in order of activation)
2. The *alternative pathway,* which includes C3, factors B and D, and properdin
3. The *membrane attack complex,* which includes C5 through C9
4. *Inhibitors* and *inactivators* of the above pathways, including C1 inhibitor, factors H and I, and C4-binding protein, or C4bp
5. *Cellular receptors* for activated or cell-bound components.

The fact that both heat-labile and heat-stable fractions of serum are necessary for the in vitro killing of microorganisms and therefore protection of animals against infection was first recognized in the late 1800s. Ehrlich subsequently named the labile fraction *complement* and the stable fraction *amboceptor,* now known to include primarily the immunoglobulins. Ferrata demonstrated in 1907 that the complement fraction included water-soluble *(pseudoglobulin)* and insoluble *(euglobulin)* components, and Pillemer showed in 1941 that complement contained at least four components. After the development of improved methods for protein purification and characterization in the 1960s, Müller-Eberhard and Nelson, among others, expanded the list to include the nine "classical" components. The current nomenclature was adopted by the World Health Organization (WHO) in 1968.

The classical pathway is activated primarily by the antibody antigen complexes. In 1913, Browning and Mackie showed that cobra venom could trigger serum-mediated lysis of erythrocytes in the absence of an antibody. Pillemer described properdin as a component of the antibody-independent complement pathway in 1954, and proposed the name *properdin pathway.* His work was not accepted until the 1960s, however, when the alternative pathway was

TABLE 20-8 Other Protease Inhibitors

Inhibitor	Molecular Mass (kDa)	Physiological Proteases Inhibited	Diseases Associated With Deficiency
α_1-Antichymotrypsin	68	Cathepsin G; mast cell chymase; prostate-specific antigen*	Hepatic cirrhosis; asthma; emphysema
α_2-Antiplasmin	70	Plasmin	Hemorrhage (increases clot lysis)
Antithrombin III†	65	Thrombin	Thromboembolism
C1 inhibitor†	104	C1r, C1s	Hereditary angioedema
Inter-α-trypsin inhibitor	160	Unknown	None known

*Several inhibitors bind and inactivate prostate-specific antigen (PSA), including α_1-antitrypsin, α_2-macroglobulin, and α_2-antiplasmin. α_1-Antichymotrypsin complexes are usually the predominant ones in serum or plasma, probably because of rapid clearance of the others. Levels of complexed PSA are increased in most patients with prostatic cancer, compared with normal individuals or those with benign prostatic hypertrophy.
†Quantitative and qualitative (functional) deficiencies reported.

shown unequivocally to exist and to be activated by bacterial lipopolysaccharides and cellular proteases or cobra venom. Activation of the classical pathway through C3 also activates the alternative pathway, which then acts to amplify the production of effector molecules.

Any of several mechanisms can activate complement, including continuous and spontaneous "tickover," activation of the classical pathway (e.g., by the antigen antibody complexes or CRP), activation of the alternative pathway, and action of proteases released by leukocytes and other inflammatory cells. The common step involved in all of these is the conversion of C3 to C3b, as shown in Figure 20-7. This figure also demonstrates the sites of action of the inhibitors and inactivators of complement (shown in gray shading), which prevent excessive or continuous depletion of the complement components in addition to controlling complement activity in sites of inflammation.

During activation, many of the complement components are enzymatically cleaved into two fragments, in general a larger fragment plus a smaller fragment that may have activity in chemotaxis, vascular permeability, and the like (see discussion below). The larger fragments are designated by a lowercase *b* and the smaller ones by a lowercase *a*. The larger fragments usually contain a binding site for membranes, immune complexes, and the like, plus in many cases an enzymatic site that can then activate the next component(s). Thus the active cell-bound fragment of C3 is C3b, whereas the anaphylatoxic peptide C3a is released into the surrounding fluid. Inactivated fragments are designated by the letter *i* (e.g., C3bi) or otherwise; for example, the persisting membrane-bound portion of C3b after inactivation is called C3d, and the major fragment after enzymatic cleavage in solution is called C3c. Activated complexes are indicated by a bar over the components (e.g., $\overline{C567}$).

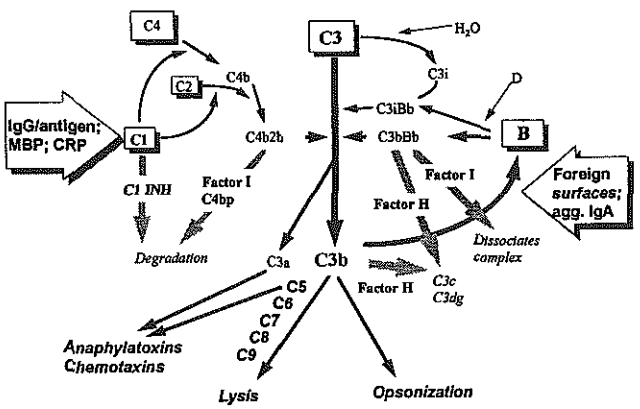

Figure 20-7 Overview of the complement cascades. Activation via the classical pathway is shown on the left and via the alternative pathway on the right. Continuous tickover by hydrolysis of C3 to C3i is shown at the center top. Direct activation of C3 by neutrophil and plasma proteases also may occur. The control mechanisms are shaded. *(Courtesy J.W. Whicher, with modifications.)*

The sequential activation of either the classical or the alternative pathway, with or without complete activation of the membrane-attack complex, produces biological effector molecules that initiate inflammation and facilitate the elimination of the antigens either by lysis (e.g., bacteria) or phagocytosis (e.g., immune complexes). A few of the specific functions of the complement system follow:

1. Some activation fragments, C3a and C5a in particular, act as anaphylatoxins and chemotaxins. Anaphylatoxin activity causes the release of histamine from mast cells, contraction of smooth muscles, and increased vascular permeability. A kinin-like fragment of C2 also increases vascular permeability, as seen in hereditary angioedema. Chemotaxin activity results in migration of phagocytes, such as polymorphonuclear leukocytes and macrophages, into areas of inflammation.
2. Membrane-, immune complex–, or cell-bound C3b acts as an opsonin, resulting in adherence of the substances to which it is bound (e.g., bacteria, viruses, or immune complexes) to specific receptors on phagocytes. They are then ingested and proteolytically destroyed. (The word *opsonin* is derived from a Greek word meaning "preparation of food for ingestion.") This is the primary route of destruction of most foreign agents, including bacteria, yeasts, and viruses, and of complement-mediated hemolysis in human beings.
3. Activation of the membrane-attack complex, through C9, can cause osmotic lysis of cells and viruses. The complete complex appears to be essential primarily for control of *Neisseria* species infections in human beings, because infections with these bacteria are the only significant clinical consequence of genetic deficiencies of the late-acting components.
4. C3d-kallikrein complexes cause the release of polymorphonuclear leukocytes from the bone marrow, increasing their availability.
5. C4b and C3b are important for solubilization of immune complexes (by disrupting lattice formation) and their removal by the reticuloendothelial system.
6. The enzymatic activity of C1s and C2b can activate the clotting, fibrinolytic, and kinin systems and platelets.
7. Interaction with cellular complement receptors is involved in regulation of the antibody response.

Thus complement is one of the major mediators of inflammation. Secondary edema and stasis permit the passage of further antibody, complement, and phagocytes into the extravascular space, aiding in the killing and removal of infectious agents and immune complexes. At the same time, thrombosis as a result of the secondary activation of platelets and the coagulation factors helps to localize infection.

In addition to the inhibitory steps shown in Figure 20-7, complement activity is also controlled by spontaneous hydrolysis of the membrane-binding sites, rapid and spontaneous dissociation of active complexes, and proteolysis by enzymes of the coagulation and fibrinolytic systems and from phagocytic cells.

TABLE 20-9 Clinical Disorders Associated With Inherited Deficiencies of Complement Components

Component	Frequency of Deficiency Gene	Associated Disorders
C1q*	Relatively rare	SLE; DLE; GN
C1r, C1s	Rare	SLE; DLE; infections
C2	≥0.0032	Recurrent infections, vasculitis; SLE, DLE (antinuclear antibody negative); one half of affected individuals are asymptomatic
C3	Rare	Severe and recurrent bacterial infections, especially with encapsulated, pyogenic bacteria (similar to immunoglobulin deficiency)
C4A	0.126	SLE, DLE
C4B	0.132	IgA nephropathy; infections
Combined C4	35% one null, 8-10% two nulls, ~1% three nulls, <0.1% total	Total deficiency: SLE, GN, DLE (many are anti-dsDNA negative but anti-Ro/SSA positive)
C5-C9	Relatively common	Severe or recurrent infections with *Neisseria* sp.
Properdin	Relatively rare	*X*-linked; neisserial infections
Factor D	Rare	Recurrent infections
Factor H or I	Rare	Hypercatabolism of C3 with secondary deficiency; severe and recurrent bacterial infections (as with C3 deficiency); membranoproliferative glomerulonephritis
C1 inhibitor	1/150,000	Hereditary angioedema (autosomal dominant)

Modified from Colten HR, Rosen FS. Complement deficiencies. Annu Rev Immunol 1992;10:809-34.
SLE, Systemic lupus erythematosus (or SLE-like disease); *DLE,* discoid lupus erythematosus; *GN,* glomerulonephritis.
*Both quantitative and qualitative (functional) deficiencies reported.

The clinical importance of the complement system is demonstrated by the disease associations seen in inherited or secondary deficiencies of the various components.[25] Several of the more important of these are listed in Table 20-9. Most of the complement components also demonstrate genetic polymorphism. The genetic aspects of C3 and C4 are discussed in the individual sections following.

The complement components are synthesized primarily by the liver, although small amounts are probably synthesized by monocytes and other cell types.

Complement C3

C3 is the functional link between the classical and alternative pathways of activation and between these pathways and the membrane-attack complex (see Figure 20-7). It is also present in the highest concentration of all the complement components in plasma and acts as a magnification factor. Structurally and genetically, C3 is related to C4, C5, and AMG, all of which contain an internal thiol ester bond that, when activated, can form complexes with membranes and other structures.[104]

Biochemistry

C3 is synthesized as a propolypeptide that is cleaved postsynthetically to two disulfide-linked chains, α (molecular mass, 110 kDa) and β (75 kDa). During the process, an internal thiol ester bond is formed in the α-chain between adjacent glutamic acid and cysteine residues. C3 contains ~3% carbohydrate, added postsynthetically. Most of the plasma C3 is synthesized by the hepatic parenchymal cells, although bacterial endotoxin induces synthesis by monocytes and fibroblasts. Catabolism is primarily by functional activation, followed by hydrolysis.

Activation of either pathway of complement results in the cleavage of C3 to C3b and C3a. The latter is released into the circulation and acts as an anaphylatoxin and a chemotaxin. C3b, with its activated thiol ester, binds to membranes and then activates the subsequent factors in the membrane-attack complex. C3b also acts as an opsonin, binding to receptors on phagocytic cells and resulting in the ingestion of bacteria, viruses, and other foreign particles by these cells.

Function

Low levels of hydrolysis, or tickover, of C3 to C3i occur constantly in plasma. C3i can bind with factor B of the alternative pathway, and the bound factor B may be cleaved by factor D. The resulting C3iBb complex is a weak C3 convertase, resulting in continuous, low-grade activation of C3. Upon activation of the classical pathway, membrane-bound C3b forms similar complexes with factor B; C3bBb is an active C3 convertase. The resulting positive feedback amplifies the complement activity many fold. Fortunately, there are mechanisms that control this; otherwise, C3 may be completely depleted, as seen in hereditary deficiency of factor H or factor I. The control mechanisms include, among others, rapid dissociation of the C3iBb and C3bBb complexes (espe-

TABLE 20-10 Diseases in Which Estimates of Complement Factors May Be Useful for Diagnosis

Disease	Complement Status
Systemic lupus erythematosus	C4 usually low, C3 sometimes low*
Rheumatoid vasculitis	C3 usually low*
Subacute bacterial endocarditis	Both C3* and C4 low
Shunt nephritis	Both C3* and C4 low
Poststreptococcal glomerulonephritis	C3 low,* usually returns to normal in 3 months
Mesangiocapillary glomerulonephritis	C3 low* (persistent), C4 normal
Polymyalgia rheumatica	C3 conversion products found
Mixed cryoglobulinemia	C3 conversion products found
Gram-negative bacteremic shock (early diagnosis)	C3 low,* C4 normal, factor B low
Gram-positive bacteremia	Both C3* and C4 low
Disseminated cytomegalovirus infection	C4 very low, C3* normal or increased

*C3 conversion products are also present.

cially in the presence of factor I), cleavage by proteases, and conversion of C3b to C3c or C3dg by factor H. Conversely, properdin and so-called nephritic factors (autoantibodies) stabilize C3bBb and protect it from the actions of factors H and I.

Clinical Significance

Increased Plasma Levels. Increased levels of C3 are seen with the APR, with biliary obstruction, and with focal glomerulosclerosis.

Acute Phase Response. C3 synthesis is induced by cytokines IL-1, IL-6, and TNFα. Levels rise modestly after trauma or surgery and during inflammatory processes (Table 20-10).

Biliary Obstruction. C3 levels are elevated in biliary obstruction in direct proportion to the level of hyperbilirubinemia.

Focal Glomerulosclerosis. In contrast to nephritic disorders, in which most patients with active disease have low levels of C3 (see later in this chapter), approximately 30% of patients with idiopathic focal glomerulosclerosis have elevated levels, which indicate a favorable prognosis.

Decreased Plasma Levels. Decreased levels of C3 are seen with genetic deficiency, acquired deficiency, and infancy.

Genetic Deficiency. Inherited primary deficiency of C3 is associated with a greatly increased risk for infection, particularly with encapsulated bacteria, similar to the picture seen with the Bruton type of agammaglobulinemia. Deficiency of the inactivators of C3, including factors H and I of the alternative pathway, is associated with severe secondary deficiency of C3 and a similar clinical picture.

Acquired Deficiency. Any cause of increased activation of C3 in vivo is usually associated with decreased plasma or serum concentrations. Disorders include the collagen vascular diseases, such as lupus nephritis, and severe infections. Activation may be through the classical or alternative pathways or both; turnover is increased and extended by the presence of C3 nephritic factor (an autoantibody that protects the alternative pathway's C3bBb convertase from degradation). In addition to increased consumption of C3, acute poststreptococcal glomerulonephritis is associated with decreased synthesis for several weeks after the onset of disease. Sequential levels of C3 may be used to monitor recovery from this disorder. Low levels in patients with systemic lupus nephritis may predict subsequent development of active nephritis, although the correlation is not high. Fulminant septicemia, in particular with *Neisseria meningitidis,* is also associated with activation of both the classical and alternative pathways and secondary hypocomplementemia, whether or not shock develops.

Infancy. Levels in neonates are approximately two thirds of adult levels, which are reached by ~1 year of age.

Genetic Aspects

C3 is coded by a gene on chromosome 19.[123] There are more than 25 known inherited variants demonstrable by prolonged agarose gel electrophoresis of serum or plasma; the most common are C3S and C3F (for "slow" and "fast," respectively). Most are associated with normal concentrations and function; one, C3f, has the same mobility as C3F but is present in approximately 50% of the normal concentration. Genetic deficiency is discussed in the Clinical Significance section above.

Laboratory Considerations

Intact C3 migrates on routine clinical electrophoresis in the β_1 region in ethylenediaminetetraacetic acid (EDTA)-treated plasma and in the β_2 region in the presence of free Ca^{2+}. However, it is a relatively labile protein, with conversion to C3c and C3dg on storage either under suboptimal conditions or for prolonged periods. These fragments migrate more anodally (α_2-β_1). Apparently reduced concentration by electrophoresis is most commonly due to in vitro conversion, not to actual deficiency. Most immunochemical

quantification methods measure C3c almost equivalently to intact C3, thus confirming normal concentration.

Electrophoretic variants, including C3F, may be confused with monoclonal immunoglobulins; their identity can be ascertained by immunofixation using specific antiserum.

Activation of C3 has been determined in the past by either immunofixation or two-dimensional, or crossed, immunoelectrophoresis of plasma, with determination of the relative amounts of C3 and C3c.[119] Currently, assays of fragments using antisera to neoantigens (such as those on C3a) are preferred for this determination. For either type of assay, plasma samples must be obtained with precautions to prevent in vitro activation by plasmin, C1s, and leukocyte proteases: The first few milliliters are discarded (or used for other purposes), then whole blood is collected through the same needle into a tube containing EDTA. Centrifugation should be performed as soon as possible and the separated plasma frozen below −40 °C.

Because of differences in immunochemical reactivity of C3 and C3c, reference materials should be completely converted to C3c and stabilized, as is the case for the international reference material CRM 470.[120]

Reference Intervals

C3 levels are low in newborns, then rise and remain relatively constant after the first year of life. The recommended reference interval for adults, based on CRM 470, is 0.9 to 1.8 g/L (90 to 180 mg/dL).[28] Levels are slightly lower in fresh serum (assayed less than 8 hours after drawing).

Complement C4

Although the existence of a fourth component of complement was proposed in 1926, the purification and characterization of C4 did not occur until the 1960s. Müller-Eberhard and Biro originally named it β_{1E}-globulin, but the name C4 was officially adopted in 1968. C4 is enzymatically cleaved by C1s after activation of C1 and is therefore the second component reacting in the classical pathway cascade. C4b, the active fragment, can then bind C2, rendering it susceptible to enzymatic cleavage by C1s. The resulting C4b2b complex is the C3/C5 convertase of the classical pathway.

Biochemistry

C4 has a molecular mass of 206 kDa, including ~4% carbohydrate. Unlike most complement components, it is relatively heat stable. Most synthesis occurs in the hepatic parenchymal cells, although some may be synthesized by monocytes or other tissue. It is originally synthesized as a single chain (proC4) but is enzymatically cleaved at two sites to form three chains, α, β, and γ, held together by disulfide bonds. It has an intramolecular thiol ester bond in the α-chain that, on activation, is the membrane-binding site for "fixation" to membranes, viruses, and immune complexes.[104]

Function

As noted previously, C4b2b is the activating enzyme for C3 and C5 in the classical pathway; C4 is essential for activation of this pathway. However, most individuals with C4 deficiency do not have problems with infection, suggesting that the alternative pathway can compensate for the lack of classical pathway activation in removal of bacterial agents; however, C4 may be critical for clearance of infecting viruses.

C4b2b bound to immune complexes prevents their precipitation and promotes immune complex clearance by the CRa receptor, especially if the C4 is the C4B isotype (see discussion later in this chapter). The binding of C4A to drugs such as procainamide and hydralazine interferes with clearance of immune complexes; this may be important in the etiology of drug-induced lupus syndromes.

C4a, the small fragment released into the circulation on activation of C4, is a weak anaphylatoxin, but its half-life in the circulation is very short.

Clinical Significance

Increased Plasma Levels. C4 levels are modestly increased by the APR (inflammation, trauma, or tissue necrosis; see Table 20-8).

Decreased Plasma Levels. C4 levels are decreased with genetic deficiency, acquired deficiency, and infancy.

Genetic Deficiency. Complete deficiency of C4 is associated with a very high prevalence of autoimmune or collagen vascular disease, particularly SLE, and in a few cases with a propensity for infection. The incidence of isolated deficiency of C4A (see discussion later in this chapter) is markedly increased in patients with SLE as well. It is not yet clear whether these correlations result from decreased clearance of immune complexes or from linkage disequilibrium with immune response genes that predispose to the development of SLE. One extended haplotype is associated with normal C4A levels in clinically normal individuals who nevertheless have anti-DNA antibodies, suggesting that both factors may be required for development of the classical disease. Approximately 20% of individuals with deficiency of IgA also have homozygous deficiency of C4A, as do some with combined IgA and IgG subclass deficiencies, suggesting that the gene for a B-cell maturation factor is linked to C4A.

Acquired Deficiency. Levels of C4 are more commonly depressed because of consumption; > 60% of individuals with SLE and low C4 levels do not have genetic deficiency. Other disorders associated with consumption and low levels include hereditary angioedema (C1 inhibitor deficiency), autoimmune hemolytic anemia, and autoimmune nephritides.

Infancy. C4 levels in newborn infants are approximately 50% to 75% of adult levels.

Genetic Aspects

C4 is coded by two nonallelic loci in the major histocompatibility complex region of chromosome 6p, closely linked to the genes for C2, factor B, and HLA-DR. The close linkage to the immune response genes may account for most of the disease associations reported for C4 variants and deficiency, rather than abnormalities of C4 itself.

The two proteins coded by the C4 loci differ by four amino acids in the binding site region of the α chain and are designated C4A and C4B (note that C4a and C4b refer instead to the cleavage products of C4 activation by C1s). The two have different binding specificities, C4A binding more efficiently with peptides (as in immune complexes) and C4B with hydroxyl groups (e.g., bacterial and erythrocyte membrane polysaccharides). C4d fragments (inactivation products of C4b) of C4A and C4B bound to erythrocyte membranes react with Rodgers and Chido blood grouping antisera, respectively.

Both of the C4 loci are highly polymorphic, with at least 13 known alleles for C4A and at least 21 for C4B, in addition to deletions and nonexpressed genes. Most of the alleles are due to substitutions in the α-chain, although a few variants of the β-chain have also been reported. Either or both loci may be deleted, unexpressed, or duplicated; as a result, a given individual may have zero to four copies of each locus. Both the total C4 level and the ratio of C4A to C4B depend on the number of copies of each locus. Most C4A variants have 25% to 35% of the hemolytic activity of the C4B alleles; one, C4A6, has little if any hemolytic activity and no C5 convertase activity.[32]

Laboratory Considerations

C4 has β_1 electrophoretic mobility, similar to that of transferrin, but is normally not visualized because of its low concentration. It is relatively fragile, especially in the presence of Ca^{2+}, so it is recommended that EDTA or citrated plasma be used for C4 assays when these are considered to be clinically important.

Functional hemolytic assays (CH50) may be used to screen for functional C4 deficiency, although the CH50 must be below 50% for deficiency to be suspected. Most assays are now done by immunochemical methods, especially immunoturbidimetry or nephelometry. Low levels alone cannot differentiate between genetic and acquired deficiency; tests for breakdown products (e.g., C4a des-arginine) or neoantigens may be helpful in detecting increased turnover.[26]

Phenotyping of the C4 proteins is usually performed by electrophoresis of neuraminidase-treated EDTA plasma, followed by immunofixation. Differentiation of overlapping C4A and C4B bands may require the use of a hemolytic gel overlay, which demonstrates primarily the C4B bands. DNA genotyping can also determine the types in most cases but cannot distinguish between synthesizing and nonsynthesizing genes. Some investigators recommend that C4 phenotyping or genotyping be performed routinely in patients with SLE if C4 levels are to be used to monitor disease activity.[117]

Reference Intervals

As with C3, levels are low in neonates but relatively constant after the first year of life. The recommended interim reference interval for adults, based on CRM 470, is 0.1 to 0.4 g/L (10 to 40 mg/dL).[28] The baseline plasma level of C4 in individuals with one or more null genes is lower.[117]

IMMUNOGLOBULINS

Immunoglobulins, or humoral antibodies, recognize the antigens and initiate mechanisms that destroy them (see Chapter 9). The ability to recognize the enormous variety of antigens is accomplished through an unusual degree of structural heterogeneity. For example, a single bacterium has numerous surface antigens; each of these has many determinants or epitopes, and each epitope stimulates production of antibodies to that determinant. This results in marked heterogeneity of the immunoglobulins, illustrated by the diffuse bands seen on electrophoresis, particularly for IgG.

Basic Biochemistry

All immunoglobulin molecules consist of one or more basic units built of two identical heavy (H) chains and two identical light (L) chains. Each of the four chains has a variable and constant region, with the variable region involved in antigen recognition and binding (see Chapter 9, Figure 9-1). The amino acid sequences of the variable regions at the *N*-terminal ends of the four chains determine the antigenic specificity of the particular antibody molecules produced by a single plasma cell or by a "clone" of identical plasma cells. The two antigen-binding sites (Fab) are at the end of each identical light- and heavy-chain pair. The remainder of the molecule, the "constant" part, is the same for every immunoglobulin molecule of a given subclass and carries the effector sites.

Although most plasma proteins are synthesized in the liver, immunoglobulins are synthesized by plasma cells, the progeny of B-lymphocyte stem cells in bone marrow (Table 20-11). More mature B lymphocytes, found mainly in lymph nodes and in blood, develop receptor immunoglobulins on their surface membranes. On encountering the antigen, these B lymphocytes proliferate and develop into plasma cells. These then secrete into the blood specific antibodies capable of binding additional antigen.

B lymphocytes at first have IgM surface receptors (see Table 20-11) and secrete IgM as the first or "primary" response to an antigen. The heavy chains of the IgM surface receptor molecules are then modified in situ to IgG or IgA heavy chains, but the variable regions remain unchanged; as the cells change into plasma cells, a second exposure to the same antigen causes a larger, secondary or anamnestic response of IgG secretion. IgM continues, however, to be synthesized against the antigens confined to the blood, such as erythrocyte surface antigens and tropical parasites.

The effector sites that interact with cells (e.g., IgE with mast cells) and with complement are on the constant (Fc) region of the heavy chains. Variations in the Fc region result in the classes and subclasses into which immunoglobulins are grouped: IgM, IgG (four subclasses), IgA (two subclasses), IgD, and IgE. Their respective heavy chains are called μ, γ, α, δ, and ε. The hinge region between the Fc and Fab portions, which is susceptible to proteolytic cleavage, controls the interaction between the Fab and Fc parts. The

TABLE 20-11 The B-Lymphocyte Series and Associated Malignant Neoplasms

Stages in Maturation and Proliferation	Principal Site	Immunoglobulins: Surface Receptor	Immunoglobulins: Secreted into Blood	Associated Malignant Neoplasms
Stem cell	Bone marrow	None	None	Acute lymphocytic leukemia
↓				
Early B lymphocyte	Lymph nodes	IgM, IgD	None	Lymphoma, chronic lymphocytic leukemia (85%)
Antigen → *Primary immune response*				
Late B lymphocyte	Lymph nodes	IgM	IgM	Lymphoma, chronic lymphocytic leukemia (15%), and Waldenström's macroglobulinemia
Antigen → *Secondary immune response*		*H-chain changes*		
Plasma cell	Lymphatic tissue, bone marrow	IgG, IgA	IgG, IgA	Multiple myeloma

hinge region contains one or more half cystines, which provide the interchain disulfide bridges. The structural variations among immunoglobulin classes also result in differences in function.[86]

Light chains, which are produced independently and in slight excess, are of two types—κ and λ—the constant regions of which have different structures. They occur in all immunoglobulins in the proportion $\kappa:\lambda = 2:1$; the two halves of a given molecule always have the same type. There are four subclasses of λ-chains. The heavy-chain genes are located on chromosome 14; κ light chains are encoded by a gene on chromosome 2, whereas the λ-chain gene is on chromosome 22.

Biochemistry of Individual Immunoglobulins

The individual immunoglobulins G, M, A, D have different biochemical properties.

Immunoglobulin G

Immunoglobulin G (IgG) is the major immunoglobulin produced by plasma cells, making up 70% to 75% of the total immunoglobulins. Of this amount, 65% is extravascular; the remainder is in plasma. IgG antibodies are produced in response to most bacteria and viruses; they bind to and aggregate small, soluble foreign proteins, such as bacterial toxins. IgG consists of two heavy and two light chains (see Chapter 9, Figure 9-1); its molecular weight is 144 to 150 kDa, including less than 3% carbohydrate. On cellulose acetate or agarose gel electrophoresis, IgG migrates broadly in the γ- and slow β-regions as a result of the heterogeneity of the IgG molecules.

Immunoglobulin G has four subclasses, IgG_1, IgG_2, IgG_3, and IgG_4, differing primarily in their hinge regions. In IgG_3, the hinge is extended by up to 15 half cystines, allowing efficient binding to C1q. Both IgG_1 and IgG_3 bind Fc receptors on phagocytic cells, activate killer monocytes (K cells), and cross the placenta by an active transport process dependent on Fc binding. IgG_1 is the principal IgG to cross the placenta and to protect neonates for the first 3 months of postnatal life. The half-life of IgG_1, like those of IgG_2 and IgG_4, is about 22 days, much longer than that of IgG_3 (7 days).

Immunoglobulin M

Immunoglobulin M is the most primitive and least specialized immunoglobulin and is the only immunoglobulin that most neonates normally synthesize. In adult serum, it is the third most abundant immunoglobulin, accounting for 5% to 10% of the total circulating immunoglobulins. IgM as a membrane receptor molecule is monomeric, but most of the serum IgM is a pentamer; each monomer is similar to the IgG molecule shown in Chapter 9, Figure 9-1, except that pentameric IgM also contains a small glycopeptide, the J chain, which is important for polymerization. Plasma cell malignancies may secrete monomeric IgM in addition to,

or instead of, pentamers. IgM's high molecular weight (970 kDa; ~10% carbohydrate) prevents its ready passage into extravascular spaces. IgM is not transported across the placenta and is therefore not involved in hemolytic disease of neonates. It is an efficient complement activator, the Fc chains being spaced at the correct distance to match the Clq-binding sites.

Immunoglobulin A

Approximately 10% to 15% of serum immunoglobulin is IgA, which contains 10% carbohydrate, has a molecular weight of 160 kDa, and has a half-life of 6 days. In its monomeric form, its structure is similar to that of IgG, but 10% to 15% of IgA in serum is dimeric, particularly IgA_2, which is more resistant to destruction by some pathogenic bacteria than IgA_1. On electrophoresis, IgA migrates in the β-γ region, anodal to most IgG.

A possibly more important form of IgA is called *secretory* IgA, found in tears, sweat, saliva, milk, colostrum, and gastrointestinal and bronchial secretions. Secretory IgA has a molecular weight of 380 kDa and consists of two molecules of IgA, a secretory component (MW 70 kDa), and a J chain (15.6 kDa). It is synthesized mainly by plasma cells in the mucous membranes of the gut and bronchi and in the ductules of the lactating breast. The secretory component makes secretory IgA more resistant to enzymes, allowing it to protect the mucosa from bacteria and viruses. Its presence in colostrum and milk probably aids in protection of neonates from intestinal infections. IgA can activate complement by the alternative pathway (see Figure 20-7), but the exact role of IgA in serum is not clear.

Immunoglobulin D

Immunoglobulin D accounts for less than 1% of serum immunoglobulins. It is monomeric, contains about 12% carbohydrate, and has a molecular weight of 184 kDa. Its structure is similar to that of IgG. Like IgM, IgD is a surface receptor for the antigen in B lymphocytes, but its primary function is unknown.

Immunoglobulin E

Immunoglobulin E is so rapidly and firmly bound to mast cells that only trace amounts of it are normally present in serum. IgE contains 15% carbohydrate and has a molecular weight of 188 kDa; its structure is similar to that of IgG. IgE binds to mast cells via binding sites on its Fc region. When the antigen (allergen) cross-links two of the attached IgE molecules, the mast cell is stimulated to release histamine and other vasoactive amines that are responsible for the vascular permeability and smooth muscle contraction occurring in such allergic reactions as hay fever, asthma, urticaria, and eczema.

Clinical Significance

Normally, serum contains a heterogeneous, polyclonal mixture of antibodies, which represent multiple "idiotypes" (i.e., the products of many different clones of plasma cells), each producing a single type of immunoglobulin molecule. Benign or malignant proliferation of one such clone produces a high concentration of a single idiotype (a monoclonal antibody), which may appear as a sharp, narrow band on protein electrophoresis. A second, fainter band of free light chains may also be visible. If a few clones proliferate, there may be several sharp bands (e.g., the oligoclonal bands seen in electrophoresis of CSF in demyelinating diseases such as multiple sclerosis, or in serum following successful bone marrow transplantation, or early during a response to such organisms as *Streptococcus pneumoniae*). Disease may therefore be associated with a decrease or an increase in the normal polyclonal immunoglobulins or an increase in one or more monoclonal idiotypes.

Immunoglobulin Deficiency

Immune defense depends on four complex, interactive systems: cell-mediated immunity (T lymphocytes); humoral antibodies (immunoglobulins); the phagocytic system; and the complement system. The last two systems are nonspecific in that they have no immunological memory for the antigen. Only the second and fourth systems are composed of plasma proteins. Immunodeficiency states characterized by recurrent infections may be the result of a defect in any one of these systems or combinations thereof.

An obvious marked reduction or absence of the γ-band on electrophoresis indicates deficiency of IgG antibodies. IgG deficiency may be secondary to protein loss or to acquired failure of synthesis, but may be due to a primary congenital disorder. The causes for various immunoglobulin deficiency disorders are listed in Box 20-1. The diagnosis of a deficiency state is clinically important because replacement therapy with IgG can be provided. Presence of a normal-appearing γ-band on protein electrophoresis does not rule out immunoglobulin deficiency. Some primary deficiencies involve only one or two immunoglobulin classes or subclasses; if the total immunoglobulin level is not greatly affected, the deficiency (e.g., IgA or an IgG subclass) may not be suspected from the electrophoretic pattern. Furthermore, some patients have normal immunoglobulin levels, but the antibodies do not react normally with the antigen.

Infants have transient physiological IgG immunodeficiency, with a nadir at about 3 months of age; either prolonged or severe physiological deficiency may be associated with increased infection rates, especially with encapsulated bacteria. Levels of maternal IgG, transferred across the placenta, rise rapidly in the fetus during the last half of pregnancy but then drop rapidly following birth (Figure 20-8). Two groups of neonates are particularly at risk: premature infants, who start with less maternal IgG, and infants in whom initiation of IgG synthesis is transiently delayed. IgG determinations are invaluable in these cases because levels may become dangerously low if therapy for the infant is not initiated. Rising IgM and normal salivary IgA concentrations

at 6 weeks of age suggest a favorable prognosis. Contact of the neonate with environmental antigens normally causes B lymphocytes to begin to multiply and IgM levels to start to rise, followed weeks to months later by IgA and IgG.

BOX 20-1 Causes of Immunoglobulin Deficiency

Secondary Causes (Common)

Defective Synthesis (IgM Falls First, Then IgA, Finally IgG)

Lymphoid malignancy, multiple myeloma, lymphoma, chronic lymphocytic leukemia
Toxic reaction (e.g., renal failure, diabetes mellitus)
Drugs (e.g., phenytoin, penicillamine)
In neonates only: prematurity, transient delay in initiation of synthesis

Abnormal Loss of Proteins

Nephrotic syndrome, burns, protein-losing enteropathy

Primary or Inherited Causes (Rare)

Failure of Antibody Production

Generalized (Severe Pyogenic Infections Occur)
Infantile X-linked Bruton's type
Acquired, variable, unclassifiable, occurring at any age
Selective immunoglobulin deficiency of
IgA: Most common (1:700), symptomless but those affected tend to suffer allergic or autoimmune disease
IgG and IgA (IgM increased): recurrent pyogenic infections
IgA and IgM: Giardiasis common
IgG: Recurrent Pyogenic Infections
IgM: Susceptibility to autoimmune disease and to septicemia following splenectomy

Combined Failure of Antibody- and Cell-Mediated Immunity

Severe combined immunodeficiency. Swiss and sex-linked types, death in infancy from fungal or viral infections
Associated with thymoma, achondroplasia, or thrombocytopenia and eczema (Wiskott-Aldrich syndrome)

Polyclonal Hyperimmunoglobulinemia

Polyclonal increases in serum immunoglobulins are the normal response to infections. IgG response predominates in autoimmune responses; IgA in skin, gut, respiratory, and renal infections; and IgM in primary viral infections and bloodstream parasites, such as malaria. *Chronic bacterial infections* may cause an increase in serum levels of all immunoglobulins. In such cases, estimations of the individual immunoglobulins seldom provide more information than protein electrophoresis. They are of value, however, in the differential diagnosis of liver disease and of intrauterine infections. In *primary biliary cirrhosis,* the IgM level is greatly increased; in *chronic active hepatitis,* IgG and sometimes IgM are increased; and in *portal cirrhosis,* IgA and sometimes IgG are increased. In *intrauterine infections,* production of IgM by the fetus increases, and the IgM level in umbilical cord blood is increased. Estimations of IgE are used in the management of asthma and other allergic conditions, especially in children.

Monoclonal Immunoglobulins (Paraproteins)

A single clone of plasma cells produces immunoglobulin molecules with identical structure. If the size of the clone increases greatly, the concentration of its particular protein in the patient's serum may produce a narrow, sharply discrete band on electrophoresis. These monoclonal immunoglobulins, termed "*paraproteins,*" may be polymers, monomers, or fragments of immunoglobulin molecules; if fragments, they are usually light chains (Bence Jones proteins) or, rarely, heavy chains or half molecules; both monomers and fragments may polymerize. About 60% of paraproteins are associated with plasma cell malignancies (multiple myeloma or solitary plasmacytoma) and approximately 15% are due to overproduction by B lymphocytes, mainly in lymph nodes (lymphomas, chronic lymphocytic leukemia, Waldenström's macroglobulinemia, or heavy-chain disease). Up to 25% of paraproteins are benign, and many are never discovered.

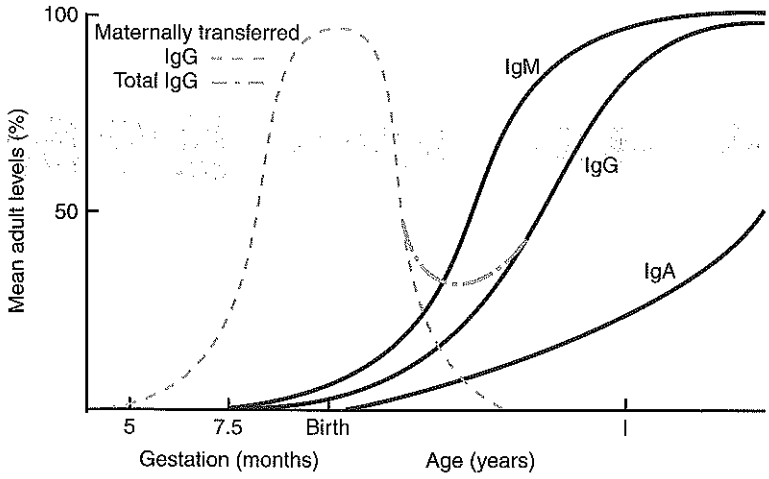

Figure 20-8 Serum immunoglobulin levels as percent of adult levels before birth and for the first year of life.

Should a paraprotein be identified in blood or urine or both, its heavy and light chains should be typed and the concentrations of polyclonal IgG, IgA, and IgM determined. These studies help to confirm whether the band on the electrophoretic pattern is indeed a paraprotein, aid in assessing prognosis, and show whether the polyclonal immunoglobulins are so low that they leave a patient vulnerable to infections. Prognosis is based on the class of the paraprotein found, its concentration at the time of diagnosis, and the rate at which its concentration increases. The concentration at the time of diagnosis usually correlates with the current extent of the disease process. The rate of increase in concentration is indicative of the rate of growth of the neoplasm.

Low-level paraproteins may be clinically benign, with normal bone marrow and bone radiographs. However, the following findings suggest that the condition may eventually become malignant:

1. IgG is greater than 2 g/dL; or either IgA or IgM is greater than 1 g/dL; or the finding of an IgD or IgE paraprotein at any concentration.
2. Immunoglobulin fragments in urine or serum: in urine, usually Bence Jones protein; in serum, occasionally other fragments, such as monomeric IgM or heavy chain fragments.
3. Progressive increase in the concentration of the paraprotein.
4. *Low levels of polyclonal immunoglobulins.*

The converse of these criteria suggests that the condition is benign or monoclonal gammopathy of unknown significance (MGUS). Even then, patients should be monitored for at least 5 years.

Multiple Myeloma. *Multiple myeloma* is a malignant neoplasm, usually of a single clone of plasma cells although occasionally two or more clones may be involved. The plasma cells most often proliferate diffusely throughout the bone marrow, but occasionally they form a solitary tumor called a *plasmacytoma.* Osteolytic bone lesions are produced, and the other bone marrow cells are reduced so that thrombocytopenia, anemia, and leukopenia develop. At the same time, development of normal clones of plasma cells is inhibited; consequently, synthesis of other immunoglobulins is reduced, and a syndrome of recurrent infections is seen. The incidence of multiple myeloma is low in individuals younger than 60 years but rises rapidly with age. Patients may present with local symptoms of a bone lesion, such as pain or fractures, but more often present with nonspecific symptoms, such as weight loss, anemia, hemorrhage, repeated infections, or renal failure. A normal serum alkaline phosphatase level in a patient with destructive bone lesions is a highly suggestive laboratory finding. Cardinal diagnostic features of the disease are the findings of neoplastic plasma cells in bone marrow aspirate, radiological demonstration of osteolytic lesions, and identification of a paraprotein in serum or urine. All patients who could conceivably have the disease should be screened for paraproteins; fewer than 1% with the disease do not have detectable paraproteins. Table 20-12 lists the paraproteins that may be associated with multiple myeloma and some characteristic findings for them.

Lymphoid Tumors. *Lymphoid tumors,* such as lymphomas or chronic lymphocytic leukemias, arise from less mature stages in B-lymphocyte development; about one in five produce paraproteins, usually of the IgM class.

Waldenström's Macroglobulinemia. If a paraprotein proves to be IgM, the diagnosis is probably *Waldenström's macroglobulinemia,* not multiple myeloma. Waldenström's macroglobulinemia clones arise from the most mature B lymphocytes and invariably produce IgM; in fact, it is the presence of this very high molecular weight protein that produces the salient symptom of the disease—an increase in viscosity of the blood. Bence Jones proteinuria occurs in 80% of these cases, but the condition is much less malignant than multiple myeloma. The lymph nodes and spleen are enlarged, but the lymphoid infiltration is slow growing, and the symptoms are usually treatable by exchange transfusion or plasmapheresis.

Heavy-Chain Disease. Rarely, unusual forms of IgG, IgA, or light chains polymerize and cause a similar syndrome with high blood viscosity. *Heavy-chain diseases* in which the paraprotein consists only of a heavy chain, usually incomplete, are rare conditions associated with lymphoid infiltration. The most common of these is *α-chain disease,* in which the intestine is infiltrated and severe malabsorption may be seen.

Cryoglobulinemia and Amyloid Disease. Both of these disorders are sometimes characterized by paraproteins. A cryoglobulin is a serum protein that precipitates at temperatures lower than normal body temperature. Most cryoglobulins are polyclonal immunoglobulin complexes, but nearly half are monoclonal, usually IgM. For cryoglobulin evaluation, a temperature of 37 °C must be maintained for blood collection and for serum separation and storage to keep the cryoglobulin from precipitating out of the serum. Amyloid disease is characterized by deposits of insoluble fibrillar protein complexes in various tissue; with special staining, the deposits are easily seen in biopsy sections. Some of the deposits contain fragments of light chains, especially from the variable region. Amyloid deposits may also occur in multiple myeloma (see discussion later in this chapter).

Laboratory Considerations

Methodologies

Immunoglobulins are most often quantified by immunoturbidimetry or immunonephelometry.[121] Immunochemical assays of polyclonal immunoglobulins involve determining the concentration of a mixture of protein molecules of different sizes having similar constant regions but different variable regions (idiotypes). Reagent antisera and reference immunoglobulin calibrators used in most immunochemical assays have been generated against normal human sera

containing a mixture of immunoglobulin subclasses and idiotypes. However, a monoclonal immunoglobulin has only a few of the determinants with which the antiserum usually reacts, and the antigen excess may be reached at relatively low concentrations. If a paraprotein is suspected or previously identified, the assays should be performed at two or more dilutions to check for this; corrected for dilution, the values should agree within ~10%. Furthermore, if a new batch of antiserum is introduced, the relationship between paraprotein concentration and the calibration curve is likely to change. For these reasons, many laboratories estimate the concentration of paraproteins by electrophoresis and densitometry.

Reference Intervals[28,106]

Reference intervals for IgG and IgM in various human adult populations differ around the world because of different degrees of antigenic stimulation. IgA levels, however, are relatively unaffected by environmental factors. Newborn infants have B lymphocytes with antigen receptors of the IgM type but do not have significant rates of immunoglobulin synthesis. Essentially all of the IgG in neonates has been transferred across the placenta from the mother. Immunoglobulin synthesis is stimulated by environmental antigens, with serum IgM rising fastest after birth (Figure 20-8).

IMMUNOGLOBULIN REFERENCE INTERVALS

Body Fluid	IgG (mg/dL)	IgA (mg/dL)	IgM (mg/dL)	IgD (mg/dL)	IgE (mg/dL)
Serum					
Newborn (4 day)	700-1480	0-2.2	5-30		
20-60 yr	700-1600	70-400	40-230	0-8	0-380
>60 yr	600-1560	90-410	30-360		
CSF	0-5.5	0-0.6	0-1.3		
Saliva	~11				

TABLE 20-12 Monoclonal Immunoglobulins (Paraproteins) in Multiple Myeloma

Plasma Paraprotein	Incidence* (%)	Age of Occurrence* (Mean)	Incidence of Bence Jones Proteinuria (%)	Comments
IgG	50	65	60	Patients more susceptible to immunodeficiency; paraproteins reach highest levels
IgA	25	65	70	Tend to have hypercalcemia and amyloidosis
Bence Jones (free light chains) only	20	56	100	Often renal failure; bone lesions; amyloidosis; poor prognosis
IgD	2	57	100	90% λ type; often have extraosseous lesion, amyloidosis, renal failure; 50% have enlarged lymph nodes, liver, spleen; poor prognosis
IgM	1	—	100	May or may not have hyperviscosity syndrome
IgE	0.1	—	Most	—
Biclonal	1	—	—	—
None detected	<1	—	0	Usually reduction of normal immunoglobulins

*Approximate.

Figure 20-8 shows in graphic form changes in IgA, IgG, and IgM levels in childhood. Readers are cautioned, however, that the data given in the figure and the listing above are only illustrative. Reference intervals change with age and with geographical and methodological differences.

Proteins in Other Body Fluids

In addition to plasma, proteins are found in several other body fluids and tissues, including urine, CSF, amniotic fluid, saliva, and feces.

Urinary Proteins[27,47,52,60]

Biochemistry and Function

The glomeruli act as an ultrafilter for plasma proteins (see Chapter 45). The degree to which individual proteins are normally filtered through the membrane is a function of their molecular size, ionic charge, and plasma concentration. In general, transport of protein molecules through the glomerular membrane progressively diminishes as protein size or negative charge increases. Normally, high molecular weight proteins, such as IgM (MW 970 kDa) appear in glomerular filtrate only in trace amounts. Relatively small yet easily detectable amounts of albumin (66.3 kDa) are passed into the filtrate as a result of its high plasma concentration and relatively low molecular weight. Proteins of MW 15 to 40 kDa filter more readily but in lesser quantities because of their low plasma concentrations.

In addition, the proportions of individual proteins excreted in the urine depend on the extent of their reabsorption by the proximal renal tubules, which is also inversely proportional to molecular size. The reabsorption of low molecular weight proteins involves binding of the protein to specific receptors on the tubule epithelial cells, uptake into the cells by pinocytosis, fusion of uptake vacuoles with lysosomes, and hydrolysis of the protein by lysosomal enzymes, followed by return of the constituent amino acids to the body pool. Very little of the total excreted urinary protein normally consists of small proteins. Only a small amount of protein is excreted normally (20 to 150 mg/dL), and most of it is albumin because of its concentration—it is not completely removed from the filtrate by the tubular cells. The remainder is almost entirely the Tamm-Horsfall protein uromucoid, a constituent of urinary casts, probably secreted by the distal tubules.

Increased permeability of the glomeruli is first signaled by increased amounts of albumin in the urine, and further increase is demonstrated by the appearance in urine of proteins with increasingly higher molecular weights. The appearance of low molecular weight proteins in urine suggests diminished or diminishing tubular reabsorption (e.g., from interstitial inflammation or toxins). (See also Chapter 45.)

Clinical Significance

In addition to hemorrhage, *proteinuria* (increased amounts of protein in urine) occurs with (1) increased glomerular permeability (*glomerular proteinuria*), in which the urinary protein is mainly albumin; (2) defective tubular reabsorption (*tubular proteinuria*), in which the urinary proteins are mainly low molecular weight proteins; (3) increased concentration in the plasma of an abnormal low molecular weight protein, such as immunoglobulin light chains (*overload proteinuria*); and (4) abnormal secretion of protein into the urinary tract (*postrenal proteinuria*). The last two are the least common and here are considered first (see Chapter 45).

Glomerular Proteinuria. This is the most common and serious type of proteinuria. Patients are routinely screened for this disorder by a simple dipstick test for albumin. If the dipstick test result is negative, clinically significant glomerular proteinuria is precluded; if the test result is positive, further investigation, such as a quantitative evaluation of protein excretion, is indicated. Because most of the excreted protein is albumin, glomerular proteinuria is often labeled *albuminuria*. An increase in glomerular permeability occurs in numerous conditions characterized by diffuse injury to the kidneys (see also Chapter 45). In diabetes, vascular permeability increases and albuminuria appears when metabolic regulation is poor, at least in part because of glycosylation and loss of negative charges on the membranes.

Immune complex disease often affects the glomeruli; in nephritis associated with SLE and in most other causes of glomerulonephritis, granular deposits containing immunoglobulins and complement components have been demonstrated on the glomerular membrane. In such progressive diffuse renal diseases, filtration of relatively small proteins, including albumin, is lost first; thus albumin levels in urine increase. As long as molecular sieving determines (by size) which proteins are filtered, the proteinuria is called *selective*. Progressively severe glomerular lesions produce less selective proteinuria until proteins of all sizes pass the glomerulus *(nonselective proteinuria)*. Changes in selectivity parallel histological changes on renal biopsy; the earliest changes are seen by electron microscopy. In the final stages of disease, as glomeruli are destroyed or become functionless, proteinuria decreases and renal failure is established. Evaluation of selectivity of the glomerular membrane is thus an aid to differential diagnosis of these diseases and their prognosis.

The protein excretion rate is ordinarily determined from a 24-hour urine collection because random specimens vary considerably in protein concentration. However, a more convenient alternative is to determine, in random samples, the ratio of protein to creatinine (protein-creatinine index). Creatinine concentration is relatively constant in any one subject, and the index correlates well with the 24-hour total excretion of protein. Total protein determination, however, does not discriminate between individual proteins, and when 24-hour excretion or protein-creatinine index values are near normal, estimation of one or two individual representative proteins is preferred. When protein excretion

exceeds 1 g/day, the proteinuria is likely to be glomerular. Heavy loss of plasma albumin (>2 g/day) is seen in the nephrotic syndrome, in association with edema. In these cases, selectivity should be assessed by electrophoresis of the urine and comparison of clearance of proteins of differing molecular weights (e.g., IgG-albumin ratio). When selectivity is high (IgG-albumin ratio <0.16), as it often is in children, treatment with corticosteroids is likely to be successful. Effect of treatment can be monitored by measuring excretion rates of total or individual proteins.

Functional or *benign proteinuria* is a form of glomerular proteinuria that is probably due to changes of blood flow through the glomeruli. It is seen with exercise, pyrexia, exposure to cold, congestive heart failure, hypertension, or arteriosclerosis. Protein excretion rates are less than 1 g/day. *Postural* or *orthostatic proteinuria,* associated with the upright position, is also a form of functional proteinuria, but excretion may exceed 1 g/day. Orthostatic proteinuria complicates assessment in otherwise symptomless patients. If transient, it is probably benign; but if chronic or not entirely related to posture, protein excretion rates should be checked at 6-month intervals, preferably by a quantitative test. Persistence of proteinuria suggests underlying renal disease. In normal pregnancy, protein excretion may increase harmlessly to 200 to 300 mg/day. This slight increase is in contrast to the proteinuria of preeclamptic toxemia, a glomerular proteinuria of up to 3 g/day, and to the proteinurias of latent renal disease or of urinary tract infection.

An additional clinical entity, *microalbuminuria,* is recognized as a strong predictor of impending nephropathy in type I diabetic patients (see Chapter 25).

Tubular Proteinuria. This type of proteinuria is characterized by the appearance of low molecular weight proteins in the urine caused by decreased reabsorption by the proximal tubules. It may occur alone but is more commonly associated with glomerular proteinuria. When tubular proteinuria occurs alone, albumin excretion is only slightly increased, but often not enough to give a positive dipstick reaction. More specific tests are required to detect simple tubular proteinuria or to identify it in the presence of glomerular proteinuria. Agarose electrophoresis of urine gives a characteristic pattern—prominent α- and β-bands, a relatively faint albumin band, and sometimes a post-γ-band. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) is even more useful because it separates proteins by molecular size (see Chapter 5) and is used to demonstrate tubular proteinuria in the presence of glomerular proteinuria. The proteins typically excreted in tubular proteinuria (molecular weights in daltons) are β_2-microglobulin (BMG; MW 11,800), lysozyme (MW 14,500), RBP (MW 21,000), α_1-microglobulin (MW 27,000), and AAG (MW 40,000), and various polypeptide hormones and enzymes. A simple way to screen for tubular proteinuria is to measure one of these, such as BMG or lysozyme, quantitatively. The protein-creatinine clearance ratio for the marker protein is a useful index of excretion (e.g., the ratio for lysozyme is increased 100 times in Fanconi syndrome) and is sufficiently reliable for most diagnostic and prognostic purposes.

Acute tubular proteinuria may occur with burns, acute pancreatitis, heavy metal poisoning, or administration of renotoxic drugs and may later resolve completely. *Chronic tubular proteinuria* is usually irreversible. Its etiology may be hereditary, as in Fanconi syndrome, or acquired, as in chronic pyelonephritis or a systemic disease, such as cirrhosis or sarcoidosis. Drugs, such as phenacetin and toxins such as cadmium, also produce tubular damage, which may be severe. In some cases, slight tubular proteinuria may be the only sign of progressive renal damage. Tests for tubular proteinuria are now being used to monitor renal allograft rejection, aminoglycoside and cadmium toxicity, and chronic pyelonephritis; BMG is a favorite marker protein.

Overload Proteinuria. This type of proteinuria includes hemoglobinuria, myoglobinuria, and Bence Jones proteinuria (high plasma concentrations of immunoglobulin light-chain paraproteins, as seen in multiple myeloma). Detection of light chains depends on electrophoretic and immunochemical testing.[40] Hemoglobin or myoglobin can be detected by tests discussed in Chapter 31.

Postrenal Proteinuria. This type of proteinuria refers to protein arising from the urinary tract below the kidneys and is usually due to inflammation or malignancy. It is diagnosed by microscopic evaluation of the urinary sediment for inflammatory cells and malignant cells. The presence of erythrocytes or leukocytes in casts in such a centrifuged urinary sediment is valuable proof that their origin is from the kidneys and is *not* extrarenal.

Laboratory Considerations

Qualitative detection of excess protein in urine is largely based on use of dipstick tests. The reactive portion of the stick is coated with a buffered indicator that develops color in the presence of protein. A typical example is Albustix (Bayer Corporation, Diagnostics Division, Tarrytown, NY), in which bromphenol blue, buffered to pH 3 with citrate, is present mostly in the protonated, yellow form. When protein is added, the affinity of the anionic form of the indicator dye for protein causes a shift of the equilibrium between anionic and protonated forms of the indicator toward formation of the blue anionic species. The intensity of the shade of blue produced is then proportional to the concentration of protein in the specimen. Combur 8 strips (Roche Diagnostics, Inc., Indianapolis, IN) are said to be less subject to drug interferences. Their detection limit is ~7 mg/dL.

Like all dye-binding techniques, the dipstick methods are more sensitive to albumin than to other plasma proteins. They are therefore excellent screening tests for glomerular proteinuria but unsatisfactory for detection of tubular proteinuria or overload proteinuria of the Bence Jones type. Although most tests measure protein in excess of 10 mg/dL, they are only roughly quantitative, and their use should be limited to screening and to rough estimates required before concentrating the specimen for electrophoresis or diluting it

for quantitative assay. A first morning urine specimen is preferred because it tends to be concentrated and unaffected by postural factors.

Quantitative assay for total protein or for individual proteins is usually performed on timed collections. Periods of 4, 8, and 12 hours may be appropriate for monitoring a renal transplant recipient or a patient whose acute renal losses of albumin are being compensated with closely regulated replacement therapy. In most cases, however, a 24-hour collection is chosen, both for quantitative total or specific protein assay and for electrophoretic separation. An alternative approach is to measure the protein/creatinine ratios of random specimens.

Quantitative assay of specific proteins is necessary for estimates of glomerular selectivity and for evaluation of tubular proteinuria. Nephelometry and turbidimetry are sufficiently sensitive for most of the analytes (see Chapters 3 and 9). More sensitive immunoassays are required for BMG because of the low levels that are typically excreted. In addition, this protein is susceptible to degradation at low pH, and specimens should be stored at a pH greater than 6.0 during the collection period. In assessment of the nephrotic syndrome, glomerular selectivity is estimated usually by measuring two individual proteins of different molecular size, such as albumin or transferrin plus IgG. A random urine sample and a corresponding serum are collected and analyzed for the two proteins. The ratio of the individual clearances is then calculated

$$\frac{\frac{UV}{P}\text{ for IgG}}{\frac{UV}{P}\text{ for albumin}}$$

where U and P represent the concentration of the compound in urine and plasma and V is the volume of excreted urine per minute. Thus V cancels out and

$$\text{Ratio} = \frac{[\text{serum albumin}] \times [\text{urine IgG}]}{[\text{urine albumin}] \times [\text{serum IgG}]}$$

A value exceeding the upper limit of the reference interval implies loss of selectivity. *Clearance* of individual proteins may also be evaluated by the classical equation

$$\text{Clearance (mL/min)} = \frac{UV}{P}$$

For evaluation of tubular proteinuria, one may use either a 24-hour specimen or a random specimen. In the latter case, the concentrations of both creatinine and the specific protein (e.g., lysozyme) are determined and the protein-creatinine index is calculated as follows:

$$\frac{\text{Lysozyme}}{\text{Creatinine}}\text{ index} = \frac{[\text{lysozyme}]}{[\text{creatinine}]}$$

Reference Intervals

The reference interval for urinary protein is 1 to 14 mg/dL.[106] The excretion rate at rest is 50 to 80 mg/d, but many laboratories indicate the reference value as less than 100 mg/d (less than 150 mg/d in pregnancy). The concentration may reach 300 mg/d in urine of healthy subjects after exercise.

Proteins in Cerebrospinal Fluid[60,115]

CSF circulates around the brain and spinal column. As described in Chapter 2, CSF for testing is normally obtained from the lumbar spinal region.

Biochemistry

CSF is secreted by the choroid plexuses, around the cerebral vessels, and along the walls of the ventricles of the brain. It fills the ventricles and cisternae, bathes the spinal cord, and is reabsorbed into the blood through the arachnoid villi. CSF turnover is rapid, exchanging totally about four times per day. More than 80% of CSF protein content originates from plasma by ultrafiltration and pinocytosis; the remainder is from intrathecal synthesis. The lowest concentration of total protein and the smallest proportion of the larger protein molecules are in the ventricular fluid; as the CSF passes down to the lumbar spine (from which site specimens are usually collected), the protein concentration increases. This difference in concentration at different levels of the CNS is illustrated by the following reference intervals:[106]

TOTAL PROTEIN (mg/dL)	
Ventricular fluid	5-15
Cisternal fluid	15-25
Lumbar fluid	15-45

In CSF from premature and full-term neonates, levels are considerably higher (up to 130 mg/dL); in healthy elderly adults, concentrations up to 60 mg/dL are considered normal.

Because CSF is mainly an ultrafiltrate of plasma, low molecular weight plasma proteins such as prealbumin, albumin, and transferrin normally predominate. No protein with a molecular weight greater than that of IgG is present in sufficient concentration to be visible on electrophoresis. The electrophoretic pattern of normal CSF after concentrating the fluid has two striking features—a prominent prealbumin band and two transferrin bands. The second of the electrophoretic transferrin bands is the τ (tau) protein band, which is produced or transformed intrathecally and, by comparison with plasma transferrin, is deficient in sialic acid content.

Clinical Significance

The blood-CSF barrier is a concept rather than an anatomical structure. The barrier is defined by the many complex

factors that govern the distribution of compounds other than water, carbon dioxide, and oxygen between the blood and the extracellular fluid of the brain and its accessory structures. In the present discussion, the term *blood-CSF barrier* is used as a synonym for the capillary endothelium of vessels of the CNS.

Examination of CSF total protein and specific proteins is used primarily to detect either increased permeability of the blood-CSF barrier to plasma proteins or increased intrathecal synthesis of immunoglobulins (Table 20-13).

Increased Permeability. The permeability of the blood-CSF barrier to plasma proteins is increased by high intracranial pressure resulting from a brain tumor, intracerebral hemorrhage, or traumatic injury. In addition, increased permeability to proteins is seen with inflammation associated with bacterial or viral meningitis, encephalitis, or poliomyelitis. Striking elevations of CSF total protein are seen in bacterial meningitis; smaller elevations occur in the other inflammatory diseases and with tumor or hemorrhage. Lumbar CSF protein is increased when the CSF circulation is mechanically obstructed above the puncture site (as by a spinal cord tumor), and plasma proteins equilibrate across the walls of meningeal capillaries into the stagnant CSF. The effect of any of these conditions is that the proportions of specific proteins in CSF increasingly resemble those in serum.

Intrathecal Synthesis. Demonstration of increased *intrathecal synthesis of immunoglobulins,* particularly IgG, has great importance in the diagnosis of demyelinating diseases of the CNS, especially multiple sclerosis.[115] In multiple sclerosis, patchy deterioration of myelin sheaths of axons in the CNS profoundly affects conduction of nerve impulses.

TABLE 20-13 Cerebrospinal Fluid Protein in Various Diseases

Clinical Condition	Appearance and Cells × 10^6/L	Total Protein (mg/dL)
Normal	Clear, colorless; 0-5 lymphocytes	15-45*
Increased admixture of proteins from blood		
Increased capillary permeability:		
Bacterial meningitis	Turbid, opalescent, purulent, usually >500 polymorphs	80-500
Cryptococcal meningitis	Clear or turbid; 50-150 polymorphs or lymphocytes	25-200
Leptospiral meningitis	Clear to slight haze; polymorphs early, then 5-100 lymphocytes	50-100
Viral meningitis	Clear or slight haze, colorless; usually up to 500 lymphocytes	30-100
Encephalitis	Clear or slight haze, colorless; usually up to 500 lymphocytes	15-100
Poliomyelitis	Clear, colorless; up to 500 lymphocytes	10-300
Brain tumor	Usually clear; 0-80 lymphocytes	15-200 (usually normal)
Mechanical obstruction:		
Spinal cord tumor†	Clear, colorless, or yellow	100-2000
Hemorrhage:		
Cerebral hemorrhage	Colorless, yellow, or bloody; blood cells	30-150
Local immunoglobulin production:		
Neurosyphilis	Clear, colorless; 10-100 lymphocytes	50-150
Multiple sclerosis‡	Clear, colorless; 0-10 lymphocytes	25-50
Both increased capillary permeability and local immunoglobulin production:		
Tuberculous meningitis	Colorless, fibrin clot, or slightly turbid; 50-500 lymphocytes	50-300 (occasionally up to 1000)
Brain abscess	Clear or slightly turbid	20-120
After myelography (inflammatory reaction)		Slight increase

*Premature infant: up to 400 mg/dL. Children: 30-100 mg/dL. Old age: up to 60 mg/dL.
†Froin's syndrome: lumbar fluid values are much higher than cisternal fluid values.
‡Similar values may occur in certain other chronic inflammatory conditions of the nervous system.

The cause of demyelination is unknown, and sites of the lesions are unpredictable; resulting symptoms vary widely. B lymphocytes that infiltrate the lesions synthesize IgG and occasionally other immunoglobulins. Because axons of the CNS are in intimate contact with CSF, the immunoglobulins produced in the lesion appear in the CSF.

Laboratory Considerations

Various analytical techniques are used to assess the increased permeability of the blood-CSF barrier to plasma proteins and to detect intrathecal synthesis of immunoglobulins.

Increased Permeability. The degree of permeability of the blood-CSF barrier is evaluated by immunochemical measurements of albumin in CSF and in serum specimens obtained at the same time. (Note that for this purpose, determination of CSF albumin must be made by a quantitative immunochemical method. Electrophoretic separation, although generally informative of increased amounts of specific plasma proteins in the CSF, is not useful for an objective definition of degree of permeability.) Albumin is a particularly suitable indicator protein because it is neither synthesized nor metabolized intrathecally. In CSF that is free of contaminating blood, albumin must necessarily have come from plasma through the blood-CSF barrier.

Using the results of quantitative albumin assays, the following ratio is calculated:

$$\frac{\text{Albumin}_{CSF}\ (g/dL)}{\text{Albumin}_{serum}\ (g/dL)}$$

However, because the quotient obtained by dividing 0.015 to 0.045 g/dL for albumin_{CSF} by 4.0 to 5.5 g/dL for albumin_{serum} would be a very small decimal value, this ratio is renamed the *CSF/serum albumin index* and is arbitrarily calculated as follows (effectively multiplying the ratio by 1000)

$$\frac{\text{CSF}}{\text{serum albumin}}\ \text{index} = \frac{\text{Albumin}_{CSF}\ (mg/dL)}{\text{Albumin}_{serum}\ (g/dL)}$$

An index value <9 is considered consistent with an intact barrier. Values of 9 to 14 are interpreted as slight impairment, 14 to 30 as moderate impairment, and >30 as severe impairment.

Intrathecal Synthesis. Determining the protein component of the fatty myelin sheath, *myelin basic protein* (MBP), is a more direct diagnostic approach to assessing diagnosing multiple sclerosis, but such assays have many difficulties because of the fragmentation of MBP in vivo by proteinases and because of the difficulties of making a specific antiserum against MBP. The assay is helpful in assessing the activity of demyelination, MBP levels rising and falling with exacerbation and remission of multiple sclerosis.[122]

Increased intrathecal synthesis of IgG causes an increase in the CSF/serum immunoglobulin concentration ratio and the appearance of oligoclonal immunoglobulin bands on electrophoretic separations of CSF. Investigation of these changes has now become routine when multiple sclerosis is suspected. At least 90% of cases of multiple sclerosis give positive findings, but increased immunoglobulins and oligoclonal immunoglobulins may also be found in some other chronic inflammatory diseases of the CNS, such as chronic meningoencephalitis caused by bacteria, viruses, fungi, or parasites; subacute sclerosing panencephalitis; and Guillain-Barré syndrome. These can be ruled out clinically or by finding a CSF total protein exceeding 100 mg/dL, a CSF leukocyte count greater than 50/μL, or a positive test result for neurosyphilis. The CSF albumin concentration in 70% of cases of multiple sclerosis is within the reference interval.

A complicating factor in testing for intrathecal IgG is that an increase in CSF IgG concentration or in the CSF/serum IgG concentration ratio may occur either because of increased permeability of the blood-CSF barrier, increased local production of IgG, or both. To identify intrathecal production specifically, correction for increased permeability is necessary. Corrections use *CSF and serum* albumin and IgG concentrations in one of several ways:

1. Concentrations *in CSF* of IgG and albumin are measured, and the following ratio is calculated:

$$\text{Ratio} = \frac{\text{IgG}_{CSF}\ (mg/dL)}{\text{Albumin}_{CSF}\ (mg/dL)}$$

   A ratio >0.27 is considered indicative of increased synthesis; in about 70% of cases of multiple sclerosis, the ratio exceeds 0.27.

2. Concentrations *in CSF and serum* of IgG and albumin are measured, and the CSF immunoglobulin index is calculated

$$\text{Index} = \frac{\text{IgG}_{CSF}\ (mg/dL) \times \text{Albumin}_{serum}\ (g/dL)}{\text{Albumin}_{CSF}\ (mg/dL) \times \text{IgG}_{serum}\ (mg/dL)}$$

   The reference interval for the index is 0.30 to 0.70. Values >0.70 are considered evidence of increased IgG synthesis; in more than 80% of cases of multiple sclerosis, this index exceeds 0.70. This estimator is now the one most often used.

3. Concentrations *in CSF and serum* of IgG and albumin are measured, and the intrathecal rate of IgG synthesis is calculated by an empirical (Tourtellotte's) formula, assessing the increase above normal of IgG in the patient's CSF and deducting from it the amount of leakage through the blood-brain barrier as indicated by excess CSF albumin. The rate of synthesis of IgG in milligrams per day is equal to

$$5\ dL/d\left[\left\{IgG_{CSF} - \frac{IgG_{serum}}{369}\right\} - \left\{\left(\text{Albumin}_{CSF} - \frac{\text{Albumin}_{serum}}{230}\right) \times \frac{0.43\,(IgG_{serum})}{\text{Albumin}_{serum}}\right\}\right]$$

All protein concentrations are expressed in milligrams per deciliter. The first bracketed term represents the difference between IgG found in CSF and the IgG expected if the blood-brain barrier is intact. The second bracketed term

represents the same for albumin but is corrected by a ratio, molecular weight of albumin/molecular weight IgG = 0.43, to express the difference in albumin as if it were a difference in IgG, assuming that 1 mol of IgG accompanies every mole of albumin that passes the blood-brain barrier. The term 5 dL/d converts milligrams per deciliter units in the other terms and relates IgG to the average volume of CSF normally formed in 24 hours (~5 dL). The number 369 is the ratio of serum/CSF IgG concentrations in normal subjects; the number 230 is the same ratio but for albumin concentrations. The reference interval for the synthesis rate is −9.9 to +3.3 mg/d. Values exceeding 8 mg/d are found in most cases of multiple sclerosis. This estimator provides no more clinical information than the IgG index; the complex formula merely rearranges the results for serum and CSF IgG and albumin and then factors in several constants.

Reference Intervals[78,106]

The reference interval for albumin in lumbar CSF by RID is 17.7 to 25.1 mg/dL. In normal CSF, IgA, IgD, and IgM are each less than 0.2 mg/dL. Reference intervals for IgG are age related; their means increase from 3.5 mg/dL in the 15- to 20-year-old age group to 5.8 in adults aged 60 years or older. A usual reference interval for CSF IgG in adults is 0.8 to 4.2 mg/dL.

Proteins in Amniotic Fluid, Saliva, Feces, and Peritoneal and Pleural Cavities

Amniotic fluid is analyzed for AFP for detection of open neural tube or abdominal wall defects in the fetus. *Saliva* is tested for secretory IgA in infantile hypogammaglobulinemia and for BMG in Sjögren's syndrome. Assay of *feces* for AAT is sometimes used in the diagnosis of exudative enteropathy, because AAT is not significantly hydrolyzed in the gut. However, intravenous injection of Cr-labeled albumin, followed by measurement of the radioactive label in feces, is a more reliable test.

Pathological accumulations of fluid in the peritoneal and pleural cavities or elsewhere vary greatly in protein content. They may be either ultrafiltrates with low protein concentrations and scant amounts of high molecular weight proteins or fluids with high protein concentrations and significant amounts of large proteins such as immunoglobulins. These fluids are divided arbitrarily according to their protein concentration into *transudates*, with total protein less than 3 g/dL, and *exudates*, with higher total protein concentrations. Transudates ordinarily reflect changes in permeability of filtering membranes, whereas exudates usually result from infection or malignancy; the latter may contain large numbers of leukocytes or malignant cells. Both transudates and exudates usually contain enough protein to allow the biuret method to be used for the determination of total protein.

Miscellaneous Proteins

Other proteins of clinical significance that are found in body tissues and fluids include amyloid, heat shock proteins, and other acute phase reactants, such as mannose binding lectin (MBL) and serum amyloid *P* (SAP).

Amyloid[71]

Amyloid (Greek, "resembling starch," because of its staining properties) is a pathological extracellular deposit that appears translucent and structureless. It stains with iodine and various dyes, but its affinity for Congo red is the basis of its definition and identification in biopsy specimens. All types of amyloid bind Congo red, which emits an apple-green fluorescence under polarized light. Under the electron microscope, all types of amyloid share two fibrillar components with characteristic periodicity and a minor rodlike P-component, a glycoprotein that, viewed on end, has the appearance of a pentamer with a hollow core. This component circulates normally in plasma. The fibril deposit consists of a characteristic β-pleated sheet, as determined by x-ray crystallography. It can be extracted from tissue with water but not physiological salt solutions.

Biochemistry

The formation of this insoluble variety of protein, resistant to normal proteolysis due to its β-conformation, is the one characteristic common to all types of amyloid, whatever their composition. Amyloid fibrils may have multiple soluble plasma protein precursors that are either increased in quantity or modified by proteolysis to make them insoluble. The result is a disease group with diverse etiologies, called *amyloidosis*. The deposits can be local or systemic. They exert pressure on vital structures and eventually cause death. No details are known about the local mechanism of formation of these deposits or the determinant for the site of deposition.

Clinical Significance

Clinically, amyloidosis is classified (omitting some rare forms) into five main groups: (1) primary amyloidosis, (2) amyloidosis associated with multiple myeloma, (3) secondary amyloidosis associated with inflammatory or infectious diseases, (4) a form associated with aging, and (5) familial amyloidosis. Increased knowledge of the chemical structure of the deposits has led to a revised classification that takes into consideration the type of amyloid protein present.[61] This classification is used in Table 20-14.

Amyloid Amyloidosis. Primary amyloidosis and amyloidosis associated with multiple myeloma are associated with immunoglobulin light-chain amyloid (AL) amyloidosis. The fibrillar proteins consist of homogeneous immunoglobulin light polypeptide chains mainly of the λ (especially λ_{VI}) type, their amino-terminal variable fragments, or both. AL proteins have a molecular weight of 14-22 kDa and have an affinity for clotting factor X, which may be responsible for the decrease in plasma level of this factor and for associated bleeding. Because they always include the variable part of the immunoglobulin light chain, they differ from one case to

TABLE 20-14 Chemical Classification of the Amyloid Diseases

Clinical Syndrome	Fibril Precursor	Fibril	Common Term	Chemical Description
Primary myeloma with amyloid	Ig L-chain	L-chain or VL fragment	AL	$A_{\lambda(1-n)}$ or $A_{\kappa(1-n)}$
Secondary (inflammation associated)	SAA	AA	AA	$AA_{prototype}$ $AA_{(trp)}$ var*

Modified from Buxbaum JN. The amyloid diseases. In: Wyngaarden JB, Smith LH Jr, editors. Cecil Textbook of Medicine. 17th ed. Philadelphia: WB Saunders, 1985:1169.

*This designation is used to denote amino acids that depart from the prototype sequences.

†Also found in other APUD (amine precursor uptake and decarboxylation) tumors.

‡Hereditary cerebral hemorrhage with amyloidosis.

§Gastroenteropancreatic neuroendocrine protein is a hormonelike peptide with no known function found to date in peptidergic central nervous system neurons, the anterior pituitary, and pancreas. Its concentration is high in cerebrospinal fluid.

another. Not all light chains seem capable of precipitation in the β-conformation that constitutes amyloid.

AL amyloidosis is the most common form of these disorders. Bone marrow plasmacytosis and excess plasma cell production of antigenically identical monoclonal light chains are common to primary amyloidosis and multiple myeloma. Thus a clear distinction between these two conditions is not possible chemically. They appear to differ only in the presence or absence of osteolytic lesions. AL deposits may occur in the tongue, heart, lymph nodes, spleen, joints, peripheral nerves, and skin.

Amyloid A Amyloidosis. Secondary amyloidosis is associated with amyloid A (AA) deposits and is called *AA amyloidosis.* In this form, AA proteins (5 to 9 kDa) are the main component and λ-light chains a minor one. AA proteins are amino-terminal fragments of serum amyloid A protein (SAA protein), composed of monomers of 12.5 kDa. It circulates in serum as a polymer of 220 to 235 kDa, most complexed to high-density lipoprotein. SAA is an acute phase protein similar to CRP, increasing rapidly in infections or noninfectious inflammation. AA protein can be distinguished from AL protein by the ability of permanganate to bleach the Congo red staining (AL protein staining is resistant).

AA protein is often deposited in chronic inflammatory diseases such as rheumatoid arthritis (incidence up to 20%) and other inflammatory joint diseases, and in chronic suppurative and granulomatous infections such as tuberculosis and osteomyelitis. Deposits of AA protein are also observed in nonlymphoid tumors such as renal and gastric carcinomas and in Hodgkin's disease. Deposits of AA protein are most often found in the kidneys, liver, and spleen, usually resulting in nephrotic syndrome and hepatosplenomegaly.

Senile Amyloidosis. Senile amyloid protein is found most often in the heart (senile cardiac amyloid), but also in the pancreas and brain. There seems to be an independent pathogenesis for these three forms. Nodular or infiltrative amyloid deposits may also be seen in the skin, lungs, and trachea and may involve endocrine organs such as the pancreas (in long-standing diabetes) or the thyroid (in medullary carcinoma). These forms usually are asymptomatic, except for the cardiac form.

Familial Amyloidosis. Several genetically transmitted forms of amyloid disease have been reported. These have primarily neurological but also renal and vascular symptoms (Table 20-14). The fibrils of the Portuguese and Swedish syndromes and the polyneuropathic amyloid syndrome of Ashkenazic Jews have monomers of 14 kDa that share antigenic determinants and amino acid homology with prealbumin (transthyretin).

Heat Shock Proteins

When exposed to heat shock or other types of stress, a large number of prokaryotic and eukaryotic cells synthesize a small family of proteins that have been termed *heat shock proteins.* These proteins complex with many other proteins, and a wide variety of physiological and molecular functions have been postulated for them. The heat shock proteins function normally as "molecular chaperones" to other proteins. For additional information on heat shock proteins, the reader is referred to reviews[48,94] and textbooks on the subject.[75,112]

Other Acute Phase Reactants

Mannose binding lectin (MBL; also called mannose binding protein) and serum amyloid P (SAP) CRP are acute phase reactants that bind to molecules—sugars or phospholipids—on the surface of infectious agents and products of cell breakdown. Both may act as acute phase reactants, but MBL levels fall during many acute infections. MLB activates C2 and C4 by way of MBL-associated proteases, bypassing C1q. Genetic deficiency or mutations may be associated with increased susceptibility to infection, malignancy, or autoimmune diseases, such as SLE and Sjögren's syndrome.[107] Like CRP, SAP is a pentraxin that, on binding, activates the classical complement pathway. Although its role is not completely known, SAP binds lipopolysaccharides, including those on gram-negative bacteria.[29]

Analysis of Proteins

Methods for the analysis of proteins in body fluids include:

1. Specific quantitative assays of particular proteins by immunochemical methods (see Chapter 9) using specific antisera and measurement of the antigen antibody complexes by nephelometry, turbidimetry, RID, or electroimmuno assay; or, if present in very low concentrations, by RIA, enzyme immunoassay (EIA), fluorescence immunoassay, or chemiluminescence.
2. Detection and identification of proteins by electrophoresis (see Chapter 5).
3. Quantification of total protein in serum, urine, and CSF.
4. Analysis by mass spectrometry, which provides structural and quantitative information (see Chapter 7).

Immunochemical Methods

Most immunochemical methods are applicable to the measurement of any of the proteins in this chapter (see Chapter 9). Because of their speed and ease, nephelometric and turbidimetric methods are most widely used for most serum proteins. These techniques are performed either by measuring the amount of Ag-Ab complex formation (equilibrium methods) or by measuring the rate of complex formation (kinetic methods). The kinetic methods are slightly faster, with measurements completed within ~20 s; however, kinetic assays are somewhat less sensitive because low-affinity antibodies do not have time to react. In addition, many kinetic methods obtain the baseline reading after addition of antiserum, which can reduce the measured signal with high-affinity antibodies.[2] A compromise is often used, with timed measurement before true equilibrium.

Assay Characteristics

Important assay characteristics for immunochemical methods include (1) limit of detection, (2) precision, and (3) turnaround time.

Limit of Detection. Detection limits of approximately 10 μg/mL (10 mg/L) have been attained with routine nephelometric and turbidimetric methods; this limit has been lowered by 10 to 100 fold using antibodies adsorbed onto latex particles. RID methods are able to detect down to a minimum of 10 to 20 μg/mL; the detection limits have been lowered even further by using special "low-level" plates (Calbiochem-Behring Corp., La Jolla, Calif.). Methods using labeled antibodies (e.g., RIA, EIA, chemiluminescence) are very sensitive and can measure levels as low as nanograms per milliliter level.

Precision. With nephelometry and turbidimetry, within-run coefficients of variation (CVs) of less than 5% are usual. RID and EIA have higher within-run and run-to-run CVs, usually in the range of 5% to 15%. RIA, measuring much smaller amounts of protein, generally has within-run CVs of 5% to 10%.

Turnaround Time. Modern nephelometric and turbidimetric methods are fast, giving results within seconds to minutes; however, equilibrium methods take longer to complete. RID requires 24 to 72 hours of incubation, an unacceptable period for stat tests. Depending on the procedure, turnaround time for RIA is usually several hours.

Instrumentation and Equipment

Nephelometric and turbidimetric methods (see Chapter 3) are performed on most current automated analytical systems, although most nephelometric assays are performed on dedicated instruments. RID requires no instrumentation other than pipettes, although some type of illuminated plate reader is advantageous. RIA requires radiation scintillation counters and an automated pipetting station.

Calibration of Immunochemical Methods

The World Health Organization (WHO) has reference preparations for the measurement of complement, immunoglobulins, and a few other proteins, but values are assigned in international units (IU). Two preparations, WHO 6HSP and the United States National Reference Preparation for Specific Human Proteins (USNRP), have values assigned in IU and in some cases mass units for 6 and 13 proteins, respectively. However, conversion factors between mass units and IU differ by as much as 16% between the two preparations.

In 1993 and 1994, the Bureau Commitaire de Référence (BCR) of the European Economic Community, the International Federation of Clinical Chemistry (IFCC), and the College of American Pathologists (CAP) jointly introduced a new reference preparation for serum proteins,[118,120] assigned in IU against WHO materials and in mass units against USNRP for albumin, AMG, complement factors C3 and C4, Cp, Hp, and IgA, IgG, and IgM. Mass values were assigned for AAT (α_1-protease inhibitor), α_1-antichymotrypsin, AAG (orosomucoid), and transferrin against highly purified and thoroughly characterized purified proteins, and for C-reactive protein against WHO 85/506, using the factor 1 IU = 1 mg/dL. In this value assignment, a rigorous transfer protocol was used, and all steps in the preparation were carefully recorded to make it possible to prepare a new lot to be as nearly the same as possible. The material is available from the Institute for Reference Materials and Methods (IRMM; Geel, Belgium) as Certified Reference Material #470 (catalog number *BCR 470*). It is intended for transfer of values to secondary reference materials (e.g., manufacturers' calibrators and controls), not for use as a working calibrator or control.

All manufacturers of immunochemical assays have referenced their individual calibrators and controls against the new material, and national and international quality control studies have shown a marked decrease in interlaboratory variance as a result. Minor differences still exist among manufacturers' assays, however, because of differences in antiserum specificity and in the methods used by the various manufacturers for transfer of values from CRM 470 to working reference materials, including differences in calibration curve fitting and in statistical methods. In most cases, the differences are less than 5%. Tentative international reference intervals for white adults have been established,[28] and the Committee on Plasma Protein Standardization of the IFCC is conducting a large-scale, prospective study to determine reference intervals for several ethnic groups. It is recommended that each laboratory confirm the validity of the values for its own population.

Optimization of Immunonephelometry and Turbidimetry Assays[2]

To minimize complexity and cost, yet retain enough accuracy and precision to meet clinical demands, most commercially available assays for proteins are a compromise In those circumstances in which these are more demanding—for example, for transferring values to a manufacturer's "gold standard" calibrators and controls—signal level should be maximized and all steps in the assay should be performed with as high precision as possible. The criteria for such an assay have been summarized by Blirup-Jensen.[2] Reference laboratories should also use this or similar protocols to maximize accuracy.

In addition, for value transfer, multiple weight-corrected dilutions of the reference (e.g., CRM 470) and the target material should be assayed in multiple runs, with the dilutions of each material calculated to be within the same section of the assay range. If possible, for optimal results, one material should be used as the calibrator and the other as the test sample to avoid the introduction of a third material and increased imprecision.[3]

Specimen Collection and Storage for Immunoassay

Test specimens should be nonhemolyzed, cell-free serum, urine, or CSF. CSF specimens may require centrifugation if cells are present. Serum and CSF samples may be stored at 2 °C to 8 °C for up to 3 days or at −20 °C for longer periods.

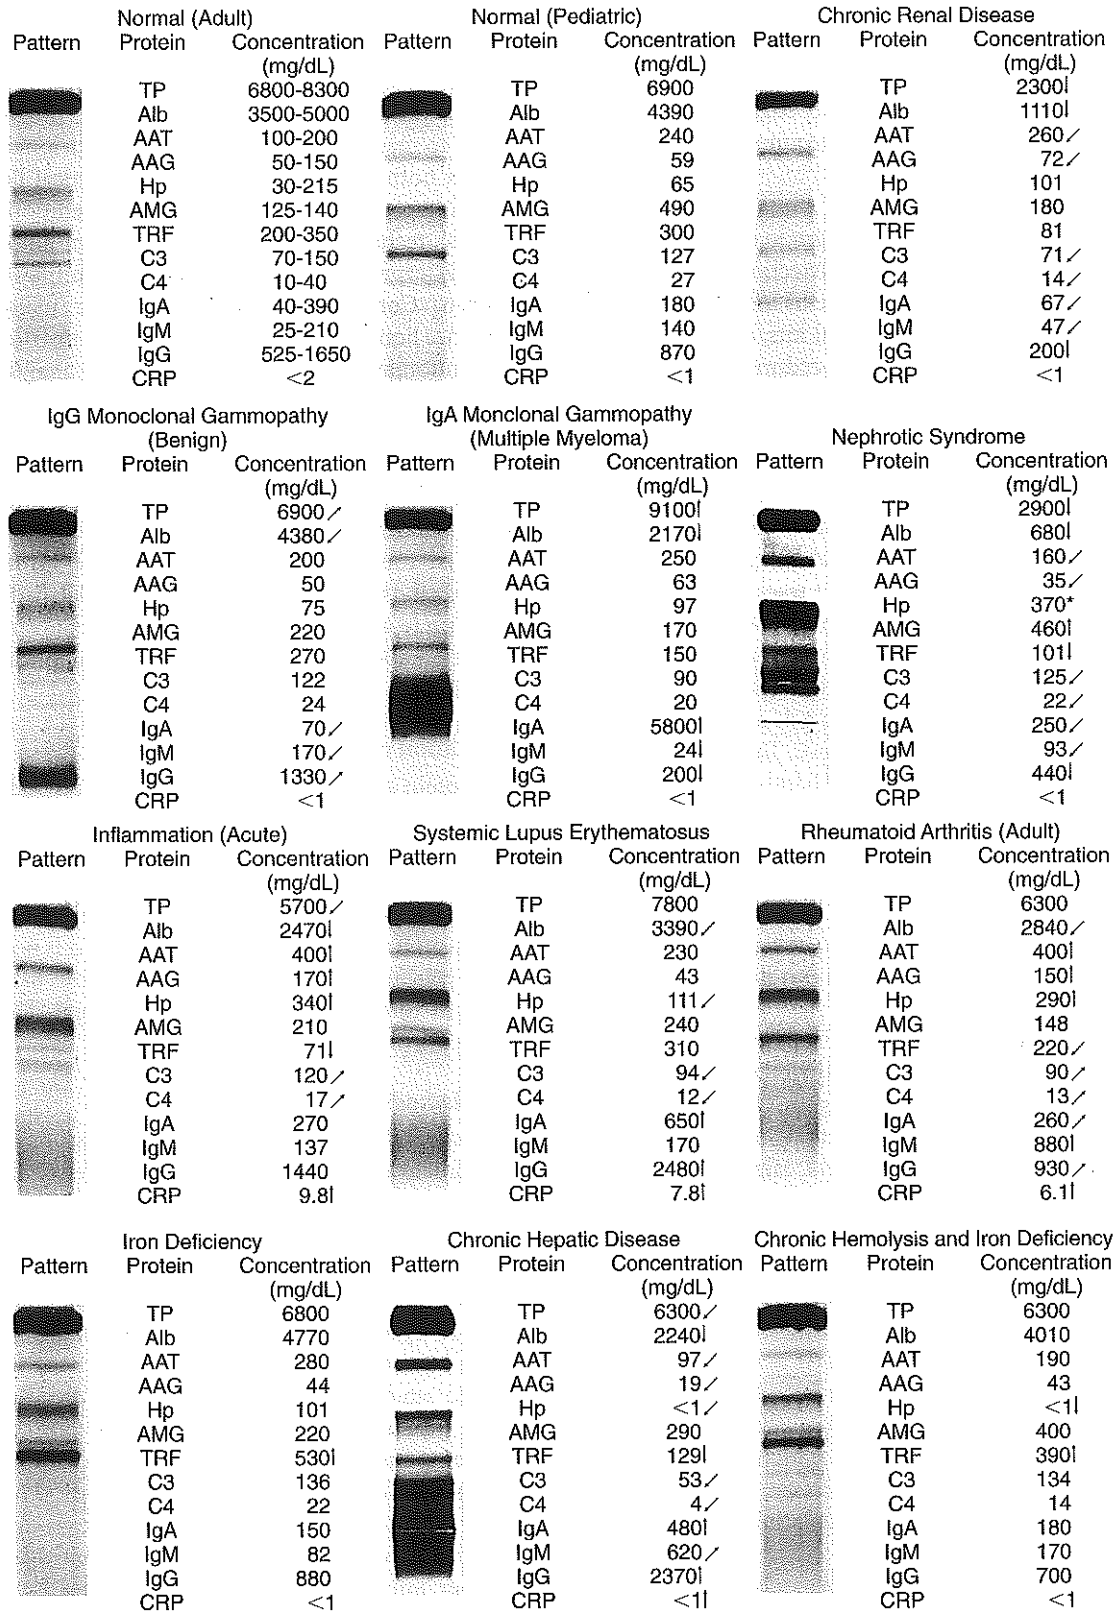
Repeated freezing and thawing of specimens may cause deterioration of many proteins and should be avoided. The minimum amount of specimen required is generally 100 µL.

Electrophoretic Techniques

Electrophoresis is used to study and measure the protein content of biological fluids (see Chapter 5). Types include serum protein electrophoresis using either cellulose acetate strip or agarose gel as the separation media, capillary electrophoresis (CE), immunofixation, and "Western blotting."

Serum Protein Electrophoresis

Separation of serum proteins on cellulose acetate or agarose gel is commonly performed on serum to avoid the fibrinogen band in a region in which monoclonal immunoglobulins often migrate. However, some analysts prefer to use plasma to semiquantify the amount of fibrinogen present as evidence of acute inflammation or in vivo fibrinolysis.



The principles of electrophoresis are described in Chapter 5. Figure 20-9 illustrates serum protein electrophoresis separations typical of normal and pathological conditions. In practice, most serum protein electrophoresis is performed using commercial systems that integrate apparatus, materials, and reagents from a single supplier. The standard buffers have low ionic strength (~0.05) and pH ~8.6. The usual sample is 3 to 5 µL, applied with a mechanical device to obtain an even stripe of sample across a track of the medium. Typical parameters for the run are 1.5 mA per 2-cm width of cellulose acetate or 10 mA per 1-cm width of agarose gel, and a run time of 40 to 60 minutes producing a 5 to 6 cm migration distance for albumin. Changes in certain bands are clearly associated with particular disorders, making serum protein electrophoresis a valuable screening method.

Coomassie brilliant blue (CBB) stain is more sensitive than Amido Black or Ponceau S and is widely used. The concentrations of many proteins are too low to be seen as distinct stained bands, or they are overshadowed by proteins of higher concentrations that migrate near them. In addition, some proteins stain poorly because they contain high proportions of lipid (lipoproteins) or carbohydrate (AAG). Densitometry may be used for rough quantification of individual bands and for graphic displays of stained electrophoresis patterns, but visual examination by a trained observer is much preferred.

Special fat stains are needed to visualize lipoproteins that migrate in bands of variable mobility in the fast α_1-region (α_1-lipoprotein), the α_2- or pre-β-region (very low density lipoprotein), and the β_1-region (β-lipoprotein), or remain at the origin (chylomicrons; see also Chapter 26). As mentioned previously, visualization of α_1-acid glycoprotein requires staining for carbohydrate side chains.

In practice, a patient's serum should always be run in parallel with a reference serum for comparison. The following changes may be seen:

1. Intensely stained bands occurring from the α- to the γ-regions in areas not containing normal proteins or free hemoglobin. These suggest monoclonal immunoglobulins (paraproteins).
2. Multiple bands, absent bands, or different mobility of normal bands. These may be due to genetic variants or deficiency, such as AAT in the α_1-region and transferrin or C3 in the β-region.
3. Other causes of altered mobility. Increased mobility of albumin occurs when it is bound to penicillin or salicylates or to greater-than-normal amounts of bilirubin or fatty acids. Mercaptalbumin dimers or complexes with AAT migrate cathodal to monomeric albumin. Decreased mobility of AAT occurs when it binds thiol groups of IgA or Bence Jones protein.
4. Appearance of a band not normally seen. The level of a low-concentration protein may increase to such a level that it becomes visible as a line. For instance, a faint, sharp band may appear between albumin and the α_1-region as a result of a 100-fold increase of AFP with certain tumors. Similarly, a large increase of CRP in a severe APR may generate a faint band in the β- or γ-region (depending on free Ca^{2+} concentration), or an increase of lysozyme in monocytic leukemia may produce a band in the post-γ-region.
5. Changes in relative concentrations. The stained strip should also be observed for changes in relative concentrations of the major plasma proteins. Such changes can suggest the presence of certain pathological conditions:
   a. Decreased albumin and γ-bands in conjunction with an increased α_2-band suggest selective protein loss, such as is displayed in the nephrotic syndrome. Note, however, that the albumin concentration must fall by at least one third of its normal level before its decrease becomes evident on the electrophoretic strip.
   b. An increase in the α_1-band (AAT and AAG) and α_2-band (Hp) suggests an APR. Prealbumin, albumin, and transferrin (α_1) are usually decreased. An increase in only AAT (α_1) may be noted in chronic hepatitis and in APRs accompanied by hemolysis, and in estrogen therapy or pregnancy. In diseases characterized by vasculitis (such as rheumatoid arthritis) or in immune complex diseases, a predominant increase in the α_2-band may be observed.
   c. An increase in the β_1-band (transferrin) suggests iron deficiency (transferrin increase) or high levels of estrogen.
   d. Fusion or bridging of β- and γ-bands suggests an increase in IgA, as seen with cirrhosis, respiratory tract or skin infections, and rheumatoid arthritis.
   e. A diffuse increase in the γ-band suggests a polyclonal γ-globulin increase associated with an immune reaction, chronic inflammatory disease, liver disease, or disseminated neoplasms. Oligoclonal bands are occasionally seen in chronic aggressive hepatitis and

Figure 20-9 Electrophoretic patterns typical of normal and of some pathological conditions (agarose gel). Upward- and downward-pointing arrows indicate increase and decrease from the reference interval, respectively. Right- or left-slanting arrows indicate variation from normal to an increase or from normal to a decrease from the reference interval, respectively. The asterisk indicates Hp 2-2 phenotype.

chronic viral infections, and in some bacterial infections (e.g., pneumococcal pneumonia) or following bone marrow transplantation.

f. Absence or decrease of the γ-band suggests immunodeficiency, either congenital or acquired.

Immunofixation Electrophoresis

Immunofixation electrophoresis (IFE) is gradually replacing immunoelectrophoresis (IEP) for detection of M-components because of its speed and ease of interpretation. Several procedures, including commercial kits, are available for both IFE and IEP. Although these procedures may differ in detail, their principles are similar.

To perform IFE analysis, aliquots of a patient's serum are placed in separate wells in an agarose gel, and their major protein groups separated by electrophoresis. One of these tracks may be treated with a chemical fixative solution to fix all proteins in the agarose and create an electrophoresis reference pattern for the specimen. The other tracks are treated with specific heavy- and light-chain antisera that react with individual immunoglobulins in the specimens, causing them to precipitate (become immunofixed) in the agarose gel. All unreacted proteins are washed out of the gel, which is then stained to visualize the fixed protein bands. By comparing the locations of the stained, immunofixed bands with a band of the same location in the reference pattern, a specific protein may be identified.

Specific antisera may be applied with saturated filter paper or cellulose acetate strips, but many commercial kits use other application methods such as mylar templates that allow direct pipetting of antiserum onto the surface of the gel.

In monoclonal gammopathies, the IFE patterns usually yield a distinct, sharply defined precipitin band with one heavy-chain and one light-chain antiserum. These bands match the location of the particular immunoglobulin in the reference pattern (Figure 20-10). A second, fainter band of free light chains may also be present.

Immunofixation electrophoresis patterns should always be confirmed by quantifying the immunoglobulins (IgG, IgA, IgM) in the specimen. Elevations of specific immunoglobulins should correspond to the more intensely stained bands on the IFE pattern, but if a monoclonal protein is present, the assayed result may be only an approximation because of antigen excess. The unaffected immunoglobulins are often very low in concentration. To determine proper dilutions of the specimen to be used for the various immunoglobulins, it is helpful to perform quantification before IFE is performed.

A comparison of IFE and IEP for two patients with monoclonal gammopathies is shown in Figure 20-10. The principles of IEP are described in Chapters 5 and 9.

Capillary Electrophoresis

CE combines the classic techniques of zone electrophoresis, isotachophoresis, isoelectric focusing, and gel electrophoresis in small-bore (10 to 100 μm), fused silica capillary tubes 20 to 200 cm in length (see Chapter 5). It is a very efficient, rapid, sensitive, and versatile analytical technique that can be used to analyze a diverse spectrum of analytes ranging from small ions to macromolecular proteins or nucleic acids.[62] CE is used for both micropreparative and analytical purposes. One advantage of CE, compared with traditional electrophoretic techniques, is its suitability for automation. However, interpretation of many abnormal samples remains a problem. Commercial systems resemble many high-performance liquid chromatography (HPLC) instruments in terms of automated sample loading and data analysis.

Western Blotting

Western blotting is similar to IFE, except that the separated proteins are blotted onto an overlaying strip of nitrocellulose or a nylon membrane by diffusion or electroblotting. The strip or membrane is then reacted with an antibody raised against the protein of interest and labeled with a radioisotope (e.g., ^{125}I) or enzyme (e.g., horseradish peroxidase). (See Chapter 5 for further details and applications of this technique.)

Determination of Serum Total Protein

In total protein assays, two assumptions are arbitrarily made: (1) All protein molecules are pure polypeptide chains, containing on the average 16% by weight of nitrogen; and (2) each of the several hundred individual proteins present in serum reacts chemically like every other protein. In practice, the first assumption is not true and the second is not always true. Nevertheless, these simplifying assumptions make measurement of total protein a practical, although empirical, procedure.

Specific Methods

Many methods have been developed to measure the total protein content of biological fluids. A number of them are reviewed here.

Biuret Method. The biuret method depends on the presence of peptide bonds, which react with Cu^{2+} ions in alkaline solutions to form a colored product whose absorbance is measured spectrophotometrically at 540 nm. A colored chelate is formed between the Cu^{2+} ion and the carbonyl oxygen and amide nitrogen atoms of the peptide bond. An analogous reaction occurs between cupric ion and the organic compound biuret, hence the name. The reaction occurs with any compound containing at least two H_2N—C—, H_2N—CH_2—, H_2N—CS—, or similar groups covalently linked directly or through a carbon or nitrogen atom. One copper ion is probably linked to six nearby peptide linkages by coordinate bonds. The intensity of the color produced is proportional to the number of peptide bonds that are reacting and therefore to the number of protein molecules present in the reaction system.

Amino acids and dipeptides do not react, but tripeptides, oligopeptides, and polypeptides react to give pink to

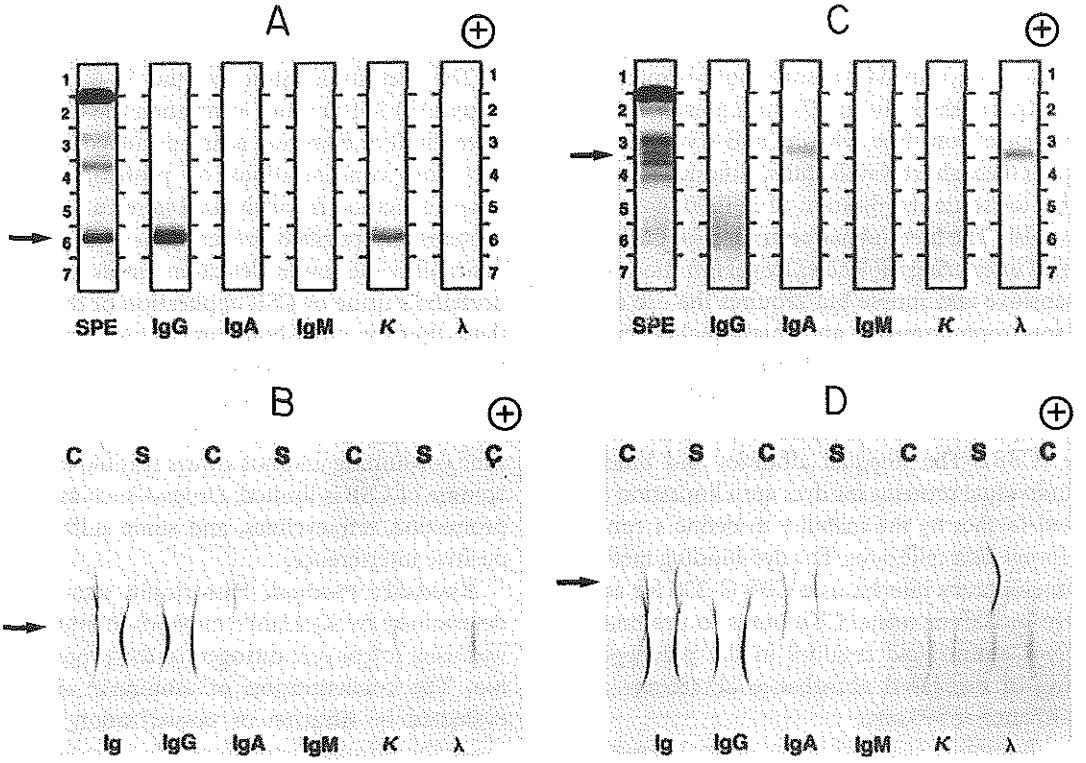

Figure 20-10 Comparison of immunofixation electrophoresis (IFE) and immunoelectrophoresis (IEP) for two patients with monoclonal gammopathies. **A**, Patient specimen with an IgG (kappa, κ) monoclonal protein as identified by IFE. The *arrow* indicates the position of monoclonal protein. *After electrophoresis, each track except SPE is reacted with its respective antiserum,* then all tracks are stained to visualize the respective protein bands. (SPE: Chemically fixed serum protein electrophoresis; IgG, IgA, IgM, κ, and λ indicate antiserum used on each track.) **B**, Same specimen as in A, with proteins identified by IEP. The *arrow* indicates the position of monoclonal protein. Normal control (C) and patient sera (S) are alternated. After electrophoresis, antiserum is added to each trough as indicated by the labels Ig (polyvalent Ig antiserum), IgG, IgA, IgM, κ, and λ. The antisera react with separated proteins in the specimens to form precipitates in the shape of arcs. The IgG and κ arcs are shorter and thicker than those in the normal control, showing the presence of the IgG (κ) monoclonal protein. The concentrations of IgA, IgM, and λ-light chains are also reduced. **C**, *Patient specimen with an IgA (lambda, λ) monoclonal protein* identified by IFE procedure as described in A. **D**, Same specimen as in C with proteins identified by IEP as described in B. The abnormal IgA and λ-arcs for the patient specimen indicate an elevated concentration of a monoclonal IgA (λ) protein. All separations were performed using the Beckman-Coulter Paragon system.

reddish-violet products. However, their concentration in serum is so low that they contribute little to the biuret color. Ammonium ions interfere but not at concentrations that can occur in serum. Most biuret methods detect between 1 and 15 mg of protein in the aliquot being measured, an amount present in 15 to 200 μL of a serum containing protein at 7 g/dL. Numerous versions of the biuret method have been reported. All the methods are sufficiently precise for clinical use.

Either serum or plasma may be used for a biuret assay. A fasting specimen is not required but may be desirable to decrease lipemia. Hemolysis should be avoided. Tightly stoppered samples of serum are stable for 1 week or more at room temperature and for 1 month at 2 °C to 4 °C. Specimens that have been frozen and thawed should be thoroughly mixed before assay.

A detailed procedure of a biuret method is available in a previous edition of this textbook.[97]

Direct Photometric Methods. Absorption of ultraviolet (UV) light at 200 to 225 nm and 270 to 290 nm is used to measure the protein content of biological samples. Absorption of UV light at 280 nm depends chiefly on the aromatic rings of tyrosine and tryptophan at pH 8. Accuracy and specificity suffer from an uneven distribution of these amino acids among individual proteins in a mixture and from the presence in body fluids of free tyrosine and tryptophan, uric

acid, and bilirubin, which also absorb light near 280 nm. At 200 to 225 nm, peptide bonds are chiefly responsible for UV absorption (70% at A_{205}); specific absorption by proteins at these shorter wavelengths is 10 to 30 times greater than at 280 nm. Interference from free tyrosine and tryptophan is also significant at these short wavelengths, although it can be made negligible for serum by dilution of 1:1000 or 1:2000 in NaCl, 0.15 mol/L. The method has been used for CSF after removal of small interfering molecules by gel filtration. This approach is sensitive and simple but requires the use of an appropriate spectrophotometer and high-quality cuvets having high transmission of light at 220 nm.

Dye-Binding Methods. Dye-binding methods are based on the ability of proteins to bind dyes, such as Coumassie brilliant blue (CBB). The unequal affinities and binding capacities of individual proteins for dyes are a limitation and are complicated further by the inability to define a consistent material for use as a calibrator. The dye-binding method of greatest contemporary interest uses CBB G-250 for assay of total protein in CSF or urine. CBB binds to protonated amine groups of amino acid residues in the polypeptide chain, resulting in decreased absorbance at 465 nm and increased absorbance at 595 nm.

The method is simple, fast, and linear up to 150 mg/dL. Run-to-run CVs with automated analysis are 5.7% at 24 mg/dL and 2.9% at 84 mg/dL. Positive interferences have been noted in urine specimens containing tolbutamide or very high concentrations of urea. Very high concentrations of sodium chloride (NaCl) and hydrogen chloride (HCl), the latter used to preserve specimens, cause very large negative interferences. If the absorbance obtained with albumin is taken as 100%, hemoglobin and transferrin give an absorbance equivalent to that for albumin, but globulins and κ and λ chains are only 60% equivalent.

Folin-Ciocalteu (Lowry) Method. Most proteins contain tyrosine, tryptophan, or both, but each protein contains a unique proportion of them. Albumin, for instance, has only 0.2% tryptophan by weight, whereas the tryptophan content of individual globulins varies between 2% and 3%. These amino acids, either free or in an unfolded polypeptide chain, reduce phosphotungstic-phosphomolybdic acid (Folin-Ciocalteu) reagent to give a blue color. Less chromogenic complexes are formed with histidine and cysteine. This property is more useful for assaying a pure protein whose composition and relative reactivity are known (e.g., fibrinogen) than it is for a mixture of individual proteins with different concentrations and reactivities. However, it has been applied to the assay of total protein (Lowry's method) as an auxiliary to the biuret reaction. In this method, proteins are allowed first to react with Cu^{2+} in alkaline solution to form copper–peptide bond–protein complexes. When the Folin-Ciocalteu reagent is added, the copper-protein complexes join with tyrosine and tryptophan residues in the reduction process. About 75% of the color produced depends on the Cu^{2+} complex; the absorbance of the colored complex is measured at a wavelength between 650 and 750 nm.

The detection limit of the Lowry method (10 to 60 μg/mL) is 100 times lower than the biuret reaction. This lower limit of detection is an advantage for measurement of very low concentrations of protein, and consequently, Lowry's method is widely used in research to measure tissue proteins and purified preparations of enzymes. Despite the desirability of lower detection limits in measuring total protein in urine or CSF, application of the Folin method to these fluids is not wholly satisfactory, because the reagents react nonspecifically with nonprotein compounds, giving a positive error of 3 to 9 mg/dL. Gel filtration can be used to remove interferents from urine or CSF, but this process is time consuming and not always feasible when the specimen volume of CSF is limited. Drugs—such as salicylates, chlorpromazine, tetracyclines, and some sulfa drugs—also give positive interference.

Kjeldahl's Method. Historically, total protein was first determined by Kjeldahl's method, in which acid digestion was used to convert nitrogen in the protein to ammonium ion. The concentration of ammonia nitrogen was then evaluated by titration or nesslerization, a correction was made for nitrogen contributed by nonprotein compounds also present in serum, and the ammonia nitrogen value was multiplied by the factor 6.25 (100%/16%) to express protein nitrogen as total protein. The method was well defined and reproducible but so time consuming and inconvenient that it was impractical for widespread routine use. This method is still used to assign values to reference materials for the biuret method.

Refractometry. Refractometry is a quick alternative to chemical analysis for serum total protein when a rapid estimate is required. Some laboratories find it a convenient way to determine total protein content before serum protein electrophoresis. At protein concentrations less than 3.5 g/dL, refractometric results are likely to be inaccurate. At a level greater than 11.0 g/dL, a valid result is obtained by diluting the serum with equal parts of water followed by reading of the diluted sample. A day-to-day CV of less than 2.0% is acceptable precision.

Nonimmunochemical Turbidimetric and Nephelometric Methods. Precipitation of protein for turbidimetric or nephelometric assays is achieved with sulfosalicylic acid alone, or with sulfosalicylic acid in combination with sodium sulfate or trichloroacetic acid (TCA), or with TCA alone. Precipitation methods for total protein assay depend on formation of a fine precipitate of uniform, insoluble protein particles, which scatter incident light in suspension.

Calibration of Total Protein Methods

Bovine or human albumin is commonly used to calibrate biuret methods. Albumin has been prepared consistently in high purity, it contains only amino acids, its nitrogen content is a constant fraction of its molecular mass, and the number

of peptide bonds per molecule is known. Because the peptide bond is the biuret-reacting unit in all proteins and the number of peptide bonds determines the absorbance of the colored product, albumin is a reasonable peptide bond reference material for all the proteins in the mixture.

For the calibration of precipitation and dye-binding methods, the recommendation is usually to use a suitable dilution of a serum (or serum pool) with a normal albumin/globulin ratio, obtained from a healthy subject, and analyzed for total protein with a correctly calibrated and well controlled biuret or Kjeldahl's method. The choice is dictated by the intent to provide in the reference material a mixture of proteins whose precipitation and dye-binding behaviors are similar to those of proteins in the sample to be analyzed. Use of bovine or human serum albumin as calibrators prohibits the use of sulfosalicylic acid because these pure proteins give about 2.5 times the turbidity given by serum globulins. With these pure proteins, TCA is the reagent of choice.

The IRMM is currently preparing a serum-based reference material for serum total protein assays, referenced to highly purified human serum albumin.

Reference Intervals

The total protein concentration of serum obtained from a healthy ambulatory adult is 6.3 to 8.3 g/dL and 6.0 to 7.8 g/dL from an adult at rest. The two general causes of alterations of serum total protein are a change in the volume of plasma water and a change in the concentration of one or more of the specific proteins in the plasma. Decrease in the volume of plasma water *(hemoconcentration)* is reflected as relative hyperproteinemia; concentrations of all the individual plasma proteins are increased. *Hyperproteinemia* is noted in dehydration caused by inadequate water intake or excessive water loss as in severe vomiting, diarrhea, Addison's disease, or diabetic acidosis. *Hemodilution* (increase in plasma water volume) is reflected as relative hypoproteinemia; concentrations of all the individual plasma proteins are decreased. Hemodilution occurs with water intoxication or salt retention syndromes, during massive intravenous infusions, and physiologically when a recumbent position is assumed. A recumbent position decreases total protein concentration by 0.3 to 0.5 g/dL and many individual proteins including albumin by up to 10%.

Of the individual serum proteins, albumin is present in such high concentrations that low levels of this protein alone may cause *hypoproteinemia.* Hypoalbuminemia is very common and has many causes. Mild *hyperproteinemia* may be caused by an increase in the concentration of specific proteins normally present in relatively low concentration, as, for example, increases in APR and polyclonal immunoglobulins as a result of infection. Marked hyperproteinemia may be caused by high levels of the *monoclonal immunoglobulins* produced in multiple myeloma and other malignant paraproteinemias.

Determination of Proteins in Urine

Many methods have been used to measure urinary proteins but none are totally satisfactory. The biuret method applied to acid-precipitated protein or to a concentrate obtained by membrane filtration has the advantage of equal sensitivity to each of the individual proteins in the mixture. Many laboratories, however, find this approach too time consuming for routine use and prefer turbidimetric and dye-binding methods because they are fast and simple. Of the dye-binding methods, pyrogallol red, Ponceau S, and CBB are the most popular. The turbidimetric and dye-binding methods have nonlinear calibration curves and unequal sensitivities for individual proteins. Most underestimate low molecular weight proteins in tubular proteinuria and immunoglobulin light chains in overload proteinuria.

To quantify urinary proteins, a timed collection is usually used. Periods of 4, 8, and 12 hours may be appropriate for monitoring a renal transplant recipient or a patient whose acute renal losses of albumin are being compensated with closely regulated replacement therapy. In most cases, however, a 24-hour collection is chosen, both for quantitative total or specific protein assay and for electrophoretic separation. An alternative approach is to measure the protein-creatinine ratios of random specimens.

Dipstick tests are often used to semiquantitatively measure excess protein in urine. With these tests, the reactive portion of the stick is coated with a buffered indicator that develops color in the presence of protein. Detection limits are approximately 7 mg/dL. Like all dye-binding techniques, the dipstick methods are more sensitive to albumin than to other plasma proteins. They are therefore excellent screening tests for glomerular proteinuria but unsatisfactory for detection of tubular proteinuria or overload proteinuria. Although most tests measure protein in excess of 10 mg/dL, they are only semiquantitative, and their use should be limited to screening and to approximate estimates required before concentrating the specimen for electrophoresis or diluting it for quantitative assay. A first morning urine specimen is preferred because it tends to be concentrated and unaffected by postural factors.

The reference interval for urinary total protein is 1 to 14 mg/dL. The excretion rate at rest is 50 to 80 mg/d, but many laboratories indicate the reference value as less than 100 mg/d (less than 150 mg/d in pregnancy). The concentration may reach 300 mg/d in urine of healthy subjects after exercise.

Determination of Total Protein in Cerebrospinal Fluid

The low levels of protein in CSF limit the methods that are used to measure total protein in it. Turbidimetric methods and versions of the CBB dye-binding method are commonly used for this purpose. The most serious disadvantage of turbidimetric methods is the requirement for 0.2 to 0.5 mL of sample. Coomassie Brilliant Blue (CBB) methods are sensitive enough for use with samples of as little as 25 µL, but they

underestimate globulins. Because albumin is the highest concentration protein in CSF, this underestimation may not be serious enough to preclude the use of a CBB method.

Determination of Specific Proteins in Cerebrospinal Fluid

Nephelometry, immunoturbidimetry, electroimmunodiffusion,[23,24] and RID are most often used for measurements of albumin and IgG in cerebrospinal fluid. Apparent absence of IgG may be due to its degradation by proteinases in the specimen. RIA is required for determination of specific proteins present in very low concentrations (e.g., IgM). The reference interval for albumin levels in lumbar CSF by RID is 17.7 to 25.1 mg/dL. IgA, IgD, and IgM, measured by RIA, are each normally less than 0.2 mg/dL. Reference intervals for IgG are age related; their means increase from 3.5 mg/dL in the 15- to 20-year-old group to 5.8 in adults aged 60 or older. The usual reference interval for CSF IgG in adults is 0.8 to 4.2 mg/dL; for total protein, 15 to 45 mg/dL. Total protein levels are considerably higher in neonates, and in healthy elderly adults, concentrations up to 60 mg/dL are considered normal.

Mass Spectrometry

Mass spectrometry is a powerful qualitative and quantitative analytical tool that is used to assess the molecular mass and primary amino acid sequence of peptides and proteins.[13,14] Technical advancements in mass spectrometry have resulted in the development of matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization techniques that allow sequencing and mass determination of picomole quantities of proteins with masses greater than 100 kDa (see Chapter 7). A time-of-flight mass spectrometer is used to detect the small quantities of ions that are produced by MALDI. In this type of spectrometer, ions are accelerated in an electrical field and allowed to drift to a detector. The mass of the ion is calculated from the time it takes to reach the detector. To measure the masses of proteins in a mixture or to produce a peptide map of a proteolytic digest, from 0.5 to 2.0 μL of sample is dried on the tip of the sample probe, which is then introduced into the spectrometer for analysis. With this technique, proteins located on the surfaces of cells are selectively ionized and analyzed.

With electrospray ionization, a fine mist of highly charged particles is produced when a liquid flows from a capillary tube into a strong electrical field (3 to 6 kV). In practice, electrospray ionization sources are often directly coupled with reversed phase HPLC or capillary columns. The ability to couple a liquid chromatograph with an electrospray ionization source and a mass spectrometer allows the online removal of salts and contaminants and the analysis of complex mixtures. Although different from MALDI, electrospray provides similar sensitivity and application to the analysis of large proteins.

Tandem mass spectrometry is a type of mass spectrometry that is applicable to the rapid sequencing of peptides contained in a complex biological mixture. In a tandem mass spectrometer, two or more mass analyzers are connected in tandem. In the first, the targeted compound is selectively ionized and its characteristic ions are separated from others in the mixture. The selected primary ions then collide with molecules of a neutral gas to produce fragments that are separated and identified in the second spectrometer. Using two mass spectrometers in tandem permits the selective and specific analysis of many compounds of various structural classes. The need for a chromatographic step is eliminated because separation and analysis take place simultaneously in the tandem mass spectrometer. Compared with older methods, tandem mass spectrometry offers greater analytical sensitivity, accuracy, and speed.

Because of its ability to identify and quantify proteins, mass spectrometry is a key analytical tool that is used in the emerging field of proteomics (see Chapter 7).[72,83,125] In proteomics, an important task is protein identification.[66] Using mass spectrometry, proteins are separated[51,90] and then digested. The resulting fragments are analyzed by mass spectrometry and used to identify the protein(s) present.[76] This process is complex and several groups are developing instrumentation and analysis software to automatically identify all the "proteins" in truly complex mixtures. Techniques employed include subcellular fractionation, multidimensional chromatography, and affinity labeling and/or purification. By combining these approaches, several thousand protein species are routinely identified.

CHAPTER 21

Enzymes*

Mauro Panteghini, M.D., Renze Bais, Ph.D., and Wouter W. van Solinge, Ph.D.

Measurements of enzymes are used in medicine in two major ways: Enzymes are measured in serum and other bodily fluids to detect injury to a tissue that makes the enzyme. Enzymes are also measured, often within a tissue, to identify abnormalities or absence of the enzyme, which may cause disease. In the first part of this chapter we discuss enzymes as markers of disease, and then describe conditions associated with abnormalities of enzymes in one readily available cell type, the erythrocyte or red blood cell. Many other abnormalities of enzymes exist, of course, and many are described in chapters of this book including Chapters 40 (Inherited Disease), 43 (Pharmacogenetics) and 55 (Inborn Errors of Amino Acid, Organic Acid, and Fastty Acid Metabolism). For descriptions of enzyme abnormalities associated with lysosomal storage disease, and tests for the related enzymes, readers are referred to the Chapter 40 Appendix that is located on this book's accompanying Evolve site, found at http://evolve.elsevier.com/Tietz/textbook/.

Injury to tissue releases cellular substances that can be used as plasma markers of tissue damage. Many of the clinically useful markers of cellular damage are enzymes. Even though various studies have shown that cytoplasmic substances can be lost following reversible cellular injury, clinical findings suggest that enzyme release is highly specific for cell death in some settings.[173] The acute myocardial cell response to ischemia is the most important example: increases of creatine kinase (CK) activity in plasma appear to occur only with myocardial necrosis.[72]

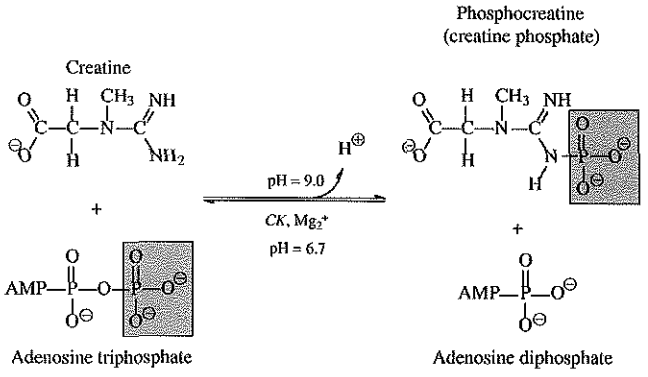
For a substance to serve as a biochemical marker of damage to a specific organ or tissue, it must arise predominantly from the organ or tissue of interest. Highly specific markers have been identified (e.g., cardiac troponin I, which is found only in cardiac myocytes). Some enzymes are predominantly found in the specialized tissue (e.g., lipase in the pancreas), while others, more widely distributed, have tissue-specific isoenzymes or isoforms (e.g., the pancreatic isoenzyme of α-amylase [AMY] or the bone isoform of alkaline phosphatase [ALP]), which can be evaluated to increase tissue and organ specificity.

The timing of the enzyme's diagnostic window is another important aspect to be considered when these markers are used to evaluate acute injuries. According to Noe,[129] the diagnostic window for an injury marker is the interval of time following an episode of injury during which plasma concentrations of the marker are increased and thereby demonstrate the occurrence of the injury. Marker substances that rapidly enter the circulation (i.e., early indicators) tend to have diagnostic windows that begin soon after the onset of the injury. On the contrary, those biomarkers that are slowly released into the circulation and/or slowly cleared from the circulation (i.e., late indicators) generally have diagnostic windows that begin later and last long after the time of injury.[129]

Several enzymes of diagnostic utility are discussed in this chapter. To better clarify their clinical meaning, the individual enzymes are discussed relative to the organ in which they are clinically most important. Overlap occurs for this classification as the same enzyme may be used for investigating disease in several organs.

MUSCLE ENZYMES

Enzymes in this category include CK, lactate dehydrogenase (LD), aldolase (ALD), and glycogen phosphorylase (GP). At the time of this book's writing, the first two are much more commonly measured than are the latter two.



*The authors gratefully acknowledge the original contributions of D.W. Moss, A.R. Henderson, and V.F. Fairbanks upon which portions of this chapter are based.

TABLE 21-1 Approximate Concentrations of Tissue Creatine Kinase (CK) Activity (Expressed as Multiples of CK Activity Concentrations in Serum) and Cytoplasmic Isoenzyme Composition

Tissue	Relative CK Activity	Isoenzymes, %		
		CK-BB	CK-MB	CK-MM
Skeletal muscle (type I, slow twitch, or red fibers)	50,000	<1	3	97
Skeletal muscle (type II, fast twitch, or white fibers)	50,000	<1	1	99
Heart	10,000	<1	22	78
Brain	5000	100	0	0
Smooth muscle:				
Gastrointestinal tract	5000	96	1	3
Urinary bladder	4000	92	6	2

Creatine Kinase

CK (EC 2.7.3.2; adenosine triphosphate : creatine N-phosphotransferase; CK) is a dimeric enzyme (82 kDa) that catalyzes the reversible phosphorylation of creatine (Cr) by adenosine triphosphate (ATP).

Physiologically, when muscle contracts, ATP is converted to adenosine diphosphate (ADP), and CK catalyzes the rephosphorylation of ADP to ATP using creatine phosphate (CrP) as the phosphorylation reservoir.

The optimal pH values for the forward (Cr + ATP → ADP + CrP) and reverse (CrP + ADP ← ATP + Cr) reactions are 9.0 and 6.7, respectively. At neutral pH, CrP has a much higher phosphorylating potential than does ATP; this higher potential favors the reverse reaction, with ATP being formed from CrP. The reverse reaction proceeds two to six times faster than the forward reaction, depending on the reaction conditions.

As is true for all kinases, Mg^{2+} is an obligate activating ion that forms complexes with ATP and ADP. The optimal concentration range for Mg^{2+} is quite narrow, and excess Mg^{2+} is inhibitory. Many metal ions, such as Mn^{2+}, Ca^{2+}, Zn^{2+}, and Cu^{2+}, inhibit enzyme activity, as do iodoacetate and other sulfhydryl-binding reagents. Activity is inhibited by excess ADP and by citrate, fluoride, nitrate, acetate, iodide, bromide, malonate, and L-thyroxine. Urate and cystine are potent inhibitors of the enzyme in serum. Even chloride and sulfate ions inhibit activity, and the concentrations of these ions should be kept low in any enzyme assay system based on the CrP + ADP (reverse) reaction. The enzyme in serum is relatively unstable, activity being lost as a result of sulfhydryl group oxidation at the active site of the enzyme. Activity can be partially restored by incubating the enzyme preparation with sulfhydryl compounds, such as *N*-acetylcysteine, monothioglycerol, dithioerythritol, dithiothreitol (Cleland reagent), and glutathione. The extent of activity recovered by this procedure is inversely proportional to the time delay in adding these reagents after collection of the blood specimen and the type of sulfhydryl reagent. The current agent of choice is *N*-acetylcysteine, used at a final concentration of 20 mmol/L in the assay reagent.

CK activity is greatest in striated muscle and heart tissue, which contain some 2500 and 550 U/g of protein, respectively. Other tissues, such as the brain, the gastrointestinal tract, and the urinary bladder, contain significantly less activity, and the liver and erythrocytes are essentially devoid of activity (Table 21-1).

CK is a dimer composed of two subunits, each with a molecular weight of about 40,000. These subunits (B and M) are the products of loci on chromosomes 14 and 19, respectively. Because the active form of the enzyme is a dimer, only three different pairs of subunits can exist: BB (or CK-1), MB (or CK-2), and MM (or CK-3). The Commission on Biochemical Nomenclature has recommended that isoenzymes be numbered on the basis of their electrophoretic mobility, with the most anodal form receiving the lowest number. Accordingly, the CK isoenzymes are numbered CK-1, CK-2, and CK-3. The distribution of these isoenzymes in the various tissues of humans is shown in Table 21-1. All three of these isoenzyme species are found in the cell in the cytosol or associated with myofibrillar structures. However, there exists a fourth form that differs from the others both immunologically and by electrophoretic mobility. This isoenzyme (CK-Mt) is located between the inner and outer

membranes of mitochondria, and it constitutes, in the heart for example, up to 15% of the total CK activity. The gene for CK-Mt is located on chromosome 15.

CK activity may also be found in macromolecular form—the so-called macro-CK. Macro-CK is found, often transiently, in sera of up to 6% of hospitalized patients, but only a small proportion of these have increased CK activities in serum. It exists in two forms, types 1 and 2. Type 1 is a complex of CK, typically CK-BB, and an immunoglobulin, often IgG, but other complexes have been described, such as CK-MM with IgA. Prevalence has been estimated as between 0.8 and 2.3%, but this is dependent on methodology and the population studied. It often occurs in women older than 50. Type 2 is oligomeric CK-Mt, with a reported prevalence of between 0.5 and 2.6%. It is found predominantly in adults who are severely ill with malignancies or liver disease or in children who have notable tissue distress. The appearance of this isoenzyme in serum is usually associated with a poor prognosis. Macro-CK can interfere with the assay of CK-MB by some immunoinhibition methods.

Both M and B subunits have a C-terminal lysine residue, but only the former can be hydrolyzed by the action of carboxypeptidases normally present in blood. Carboxypeptidases B (EC 3.4.17.2) or N (arginine carboxypeptidase; EC 3.4.17.3) sequentially hydrolyze the lysine residues from CK-MM to produce two CK-MM isoforms—CK-MM_2 (one lysine residue removed) and CK-MM_1 (both lysine residues removed). The loss of the positively charged lysine produces a more negatively charged CK molecule with greater anodic mobility. Because CK-MB has only one M subunit, the dimer coded by the M and B genes is named CK-MB_2 and the lysine-hydrolyzed dimer is named CK-MB_1. The assay of the CK isoforms requires special techniques, such as high-voltage electrophoresis (with gel cooling), high-performance liquid chromatography (HPLC), chromatofocusing, or immunoassay.[141]

Serum CK activity is subject to a number of physiological variations. Sex, age, muscle mass, physical activity, and race all interact to affect serum activities.

Clinical Significance

Serum CK activity is greatly elevated in all types of muscular dystrophy. In progressive muscular dystrophy (particularly Duchenne sex-linked muscular dystrophy), enzyme activity in serum is highest in infancy and childhood (7 to 10 years of age) and may be increased long before the disease is clinically apparent. Serum CK activity characteristically falls as patients get older and as the mass of functioning muscle diminishes with the progression of the disease. About 50% to 80% of the asymptomatic female carriers of Duchenne dystrophy show threefold to sixfold increases of CK activity, but values may be normal if specimens are obtained after patients have experienced a period of physical inactivity. Quite high values of CK are noted in viral myositis, polymyositis, and similar muscle diseases. However, in neurogenic muscle diseases, such as myasthenia gravis, multiple sclerosis, poliomyelitis, and parkinsonism, serum enzyme activity is normal. Very high activity is also encountered in malignant hyperthermia, a familial disease characterized by high fever and brought on by administration of inhalation anesthesia (usually halothane) to the affected individual. Apparently, CK-MB replaces part of the CK-MM form in the muscles, resulting in impaired storage of CrP in muscle.

Skeletal muscle that is diseased or damaged (such as by extreme exercise) may contain significant proportions of CK-MB owing to the phenomenon of "fetal reversion," in which fetal patterns of protein synthesis reappear. Thus serum CK-MB isoenzyme may increase in such circumstances. This explanation may also account for the elevated CK-MB values sometimes observed in chronic renal failure (uremic myopathy).

In acute rhabdomyolysis due to crush injuries, with severe muscle destruction, serum CK activities exceeding 200 times the upper reference limit may be found. Serum CK can also be increased by other direct trauma to muscle, including intramuscular injections and surgical interventions. Finally, a number of drugs at pharmacological doses can increase serum CK activities.

The changes of serum CK and its MB isoenzyme following a myocardial infarction are discussed in Chapter 44. Other cardiac conditions have been reported to increase serum CK and CK-MB in serum. These conditions include cardioversion, cardiopulmonary bypass and coronary artery bypass surgery, cardiac transplantation, myocarditis, pericarditis, and pulmonary embolism. Despite improvements in the diagnostic performance and practicality of CK and CK-MB assays, there is no controlled clinical impact trial showing that these tests are effective for decisions to send a patient home or to the appropriate level of care of admission for patients with suspected acute cardiac ischemia, either as one-time or serial tests.[15,182] For diagnosis of acute myocardial infarction, it is now advantageous to use more cardiac-specific nonenzymatic tests, such as cardiac troponin I or T.

Serum CK activity demonstrates an inverse relationship with thyroid activity. About 60% of hypothyroid subjects show an average elevation of CK activity fivefold more than the upper reference limit; elevations of as high as fiftyfold have also been found. The major isoenzyme present is CK-MM, suggesting muscular involvement.

During normal childbirth there is a sixfold elevation in maternal total serum CK activity. Surgical intervention during labor further increases the activity of CK in serum. CK-BB may be elevated in neonates, particularly in brain-damaged or very low birth weight newborns. The presence of CK-BB in blood, usually at low concentrations, may however represent a normal finding in the first days of life.

Methods for the Determination of Creatine Kinase Activity*

Numerous photometric, fluorometric, and coupled enzyme methods have been developed for the assay of CK activity, using either the forward (Cr → CrP) or the reverse (Cr ← CrP) reaction. Analytically the reverse reaction is preferred because it proceeds about six times faster than the forward reaction, although the cost of the starting chemicals, CrP and ADP, is greater than the cost of creatine and ATP.

$$\text{Creatine phosphate} + \text{ADP} \xrightarrow[\text{pH 6.7}]{CK} \text{creatine} + \text{ATP}$$

$$\text{ATP} + \text{glucose} \xrightarrow{HK} \text{glucose-6-phosphate} + \text{ADP}$$

$$\text{Glucose-6-phosphate} + \text{NADP}^{\oplus} \xrightarrow{G6PD} \text{6-phosphogluconate} + \text{NADPH} + \text{H}^{\oplus}$$

CK catalyzes the conversion of CrP to Cr with a concomitant phosphorylation of ADP to ATP.

The ATP produced is measured by hexokinase (HK)/glucose-6-phosphate dehydrogenase (G6PD) coupled reactions that ultimately convert $NADP^+$ to NADPH, which is monitored spectrophotometrically. Oliver first reported this method that Rosalki also described with the improvement of adding AMP to inhibit adenylate kinase (AK) and cysteine to activate CK.[11] Subsequently, Szasz and colleagues optimized the assay by adding *N*-acetylcysteine to activate CK, EDTA to bind Ca^{2+} and to increase the stability of the reaction mixture, and adenosine pentaphosphate (Ap_5A) in addition to AMP to inhibit AK.[11] A reference method based on this previous experience was developed by the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC); it was modified recently to produce a reference procedure for the measurement of CK at 37 °C.[175]

CK activity in serum is relatively unstable and is rapidly lost during storage. The degree of instability varies among specimens. Average stabilities are less than 8 hours at room temperature, 48 hours at 4 °C, and 1 month at –20 °C. CK is susceptible to thermal denaturation; the degree of inactivation corresponds to the degree of temperature increase and is not reversed by addition of sulfhydryl (thiol) reagents. Therefore the serum specimen should be chilled to 4 °C if the serum is not analyzed immediately. It is not necessary to add any thiol agent for storage because the optimized assay formulation, containing EDTA, 2 mmol/L, and *N*-acetylcysteine, 20 mmol/L, reactivates CK in serum to the extent of 99% after it has been stored for 1 week at 4 °C. A slight degree of hemolysis is tolerated because erythrocytes contain no CK activity. However, moderately or severely hemolyzed specimens are unsatisfactory because enzymes and intermediates (AK, ATP, and G6P) liberated from the erythrocytes may affect the lag phase and the side reactions occurring in the assay system.

*Methodological details for many of the muscle, liver, pancreatic, and bone methods discussed later in this chapter are found in a prior edition of this textbook (Moss DW, Henderson AR. Clinical enzymology. In: Burtis CA, Ashwood ER eds. Textbook of clinical chemistry, 3rd ed. WB Saunders: Philadelphia, 1999:617-721.)

Reference Intervals

Serum CK activity is influenced by age, sex, race, lean body mass, physical activity, and other less defined genetic differences. The distributions of CK activity are notably skewed toward higher values in reference populations. Men have higher values than women, and blacks have higher values than nonblacks. In Caucasian subjects, the reference interval was found to be 46 to 300 U/L for males and 34 to 180 U/L for females when measured at 37 °C.[8] Experience with the IFCC 37 °C reference procedure has shown reference intervals of 46 to 171 U/L for males and 34 to 145 U/L for females.[180]

Exercise and muscle trauma can increase serum CK. Sustained exercise, such as in well-trained long-distance runners, increases the CK-MB content of skeletal muscle, which may produce abnormal serum CK-MB concentrations.

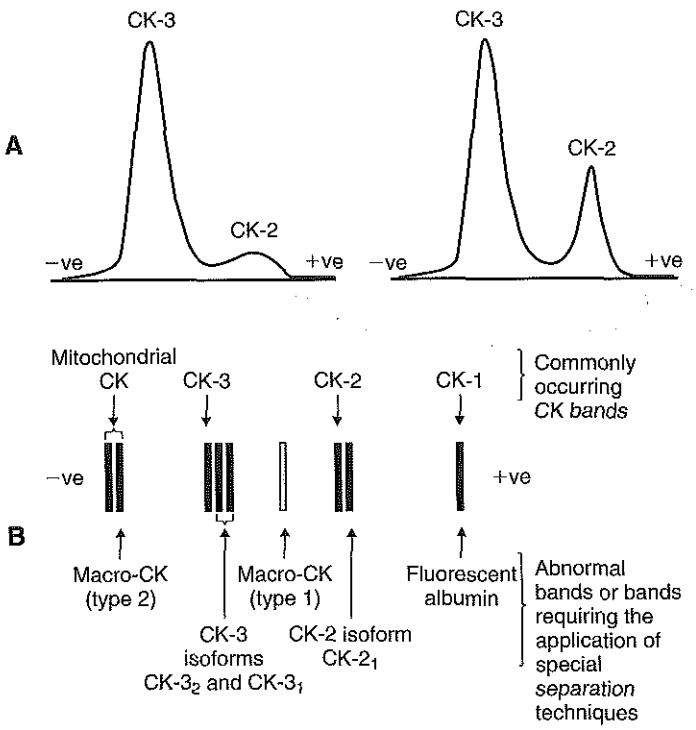
Methods for the Separation and Quantification of Creatine Kinase Isoenzymes

The techniques most commonly used are electrophoresis and various immunological methods.

Electrophoretic methods for CK isoenzymes use agar, agarose, or cellulose acetate. The isoenzyme bands are visualized by incubating the support with a concentrated CK assay mixture using the reverse reaction. The NADPH formed in this reaction is then detected by observing the bluish-white fluorescence after excitation by long-wave (360 nm) ultraviolet light. NADPH may be quantified by fluorescent densitometry, which is capable of detecting 2 to 10 U/L. Typical examples of results obtained by this technique on a serum sample of a healthy adult and for a patient who has suffered a myocardial infarction 24 hours previously are shown in Figure 21-1, *A*. Alternatively the NADPH can reduce a tetrazolium salt to form a colored formazan. The discriminating power of electrophoresis allows the detection of many abnormal bands, many of which are shown in Figure 21-1, *B*.

In immunoinhibition techniques for measurement of CK-MB, an anti-CK-M subunit antiserum is used to inhibit both M subunits of CK-MM and the single M subunit of CK-MB and thus allow determination of the enzyme activity of the B subunit of CK-MB, the B subunits of CK-BB, macro-CKs, and AK. To determine CK-MB, this technique assumes the absence of CK-BB (and of the other sources of interference mentioned earlier) from the tested serum, a circumstance that does not always occur. In a variation of this technique, the combined activity of the BB isoenzyme, AK, and macro-CKs is determined in a separate reaction and subtracted. The immunoinhibition techniques have been largely supplanted by mass assays of CK-MB.

In contrast with immunoinhibition, which measures the CK-MB isoenzyme by determination of its catalytic activity,



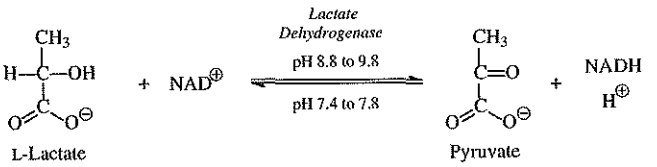


Figure 21-1 A, The electrophoretic separation of serum CK isoenzymes from a healthy adult *(left)* and from a patient *(right)* who had a myocardial infarction 24 hours previously. **B,** A diagrammatical representation of the CK isoenzymes (some of which are only seen in disease) and of some of the reported anomalous forms.

immunoassays measure CK-MB mass concentrations. Specific measurements of CK-MB use the "sandwich" technique, in which two antibodies having affinity for different parts of the CK-MB dimer are used. One antibody may be directed against the B-subunit and the other against the M-subunit; an antibody that recognizes only the MB dimer is also used in some assays. The first antibody, which is usually monoclonal, is rendered immobile on a matrix, and the second antibody is conjugated with a label, such as an enzyme or a marker molecule. The sandwich technique ensures that only CK-MB is estimated, because neither CK-MM nor CK-BB reacts with both antibodies. Mass assays are more sensitive than activity-based methods and will detect CK-MB elevations earlier. A number of mass assays, using various labels, are now commercially available and are used for routine and emergency assay of CK-MB. The limit of detection of these systems for CK-MB is usually less than 1 µg/L. The upper reference limit for males is 5.0 µg/L, with values for females being less than the male values, although many laboratories use a single reference limit (male).[136]

Lactate Dehydrogenase

Lactate dehydrogenase (EC 1.1.1.27; L-lactate: NAD^+ oxidoreductase; LD) is a hydrogen transfer enzyme that catalyzes the oxidation of L-lactate to pyruvate with the mediation of NAD^+ as a hydrogen acceptor.

As indicated, the reaction is reversible, and the reaction equilibrium strongly favors the reduction of pyruvate to lactate (P → L)—*the "reverse reaction."*

The pH optimum for the lactate-to-pyruvate (L → P) reaction is 8.8 to 9.8, and an assay mixture, optimized for LD-1 at 37 °C, contains NAD^+, 9 mmol/L, and L-lactate, 80 mmol/L. For the P → L assay, at 37 °C, the pH optimum is 7.4 to 7.8, NADH 300 µmol/L, and pyruvate 0.85 mmol/L. The optimal pH varies with the predominant isoenzymes in the sample and depends on the temperature and on substrate and buffer concentrations. The specificity of the enzyme extends from L-lactate to various related 2-hydroxyacids and 2-oxo-acids.[107] The catalytic oxidation of 2-hydroxybutyrate, the next higher homologue of lactate, to 2-oxobutyrate is referred to as 2-hydroxybutyrate dehydrogenase (HBD) *activity. LD does not act on* D-*lactate, and only* NAD^+ serves as a coenzyme.

The enzyme has a molecular weight of 134,000 and is composed of four peptide chains of two types: M (or A) and H (or B), each under separate genetic control. The structures of LD-M and LD-H are determined by loci on human chromosomes 11 and 12, respectively. The subunit compositions of the five isoenzymes, in order of decreasing anodal mobility in an alkaline medium, are LD-1 (HHHH; H_4); LD-2 (HHHM; H_3M); LD-3 (HHMM; H_2M_2); LD-4 (HMMM; HM_3); and LD-5 (MMMM; M_4). A different, sixth LD isoenzyme, LD-X (also called LD_c), composed of four X (or C) subunits, is present in postpubertal human testes. A seventh LD, called LD-6, has been identified in the sera of severely ill patients.

LD is inhibited by reagents with reactivity against thiol groups, such as mercuric ions and *p*-chloromercuribenzoate, the inhibition being reversed by the addition of cysteine or glutathione. Borate and oxalate inhibit by competing with lactate for its binding site on the enzyme; similarly, oxamate competes with pyruvate for its binding site. Both pyruvate and lactate in excess inhibit enzyme activity, although the effect of pyruvate is greater. Inhibition by either substrate is greater for the H form than for the M form, and substrate inhibition decreases with increase in pH. EDTA inhibits the enzyme perhaps by binding Zn^{2+}; however, the postulated activator role for zinc ions is not fully established.

LD activity is present in all cells of the body and is invariably found only in the cytoplasm of the cell. Enzyme concentrations in various tissues are about 500 times greater than those normally found in serum. Therefore leakage of the enzyme from even a small mass of damaged tissue increases the observed serum activity of LD to a significant extent. Different tissues show different isoenzyme composition. In cardiac muscle, kidneys, and erythrocytes, the

electrophoretically faster moving isoenzymes LD-1 and LD-2 predominate, whereas in liver and skeletal muscle, the more cathodal LD-4 and LD-5 isoenzymes predominate—although skeletal muscle damage may also result in anodic LD patterns. Isoenzymes of intermediate mobility account for the LD activity from many sources (e.g., spleen, lungs, lymph nodes, leukocytes, and platelets).

Clinical Significance

Because of its wide distribution in all tissues, serum LD elevations occur in a variety of clinical conditions—including myocardial infarction, hemolysis and disorders of the liver, kidneys, lung, and muscle. A systematic review of the literature concluded that serum LD is relevant in the diagnosis of myocardial infarction, hemolytic anemia, ovarian dysgerminoma, and testicular germ cell tumor.[68] For monitoring purposes, LD is relevant in predicting the survival duration and rate in Hodgkin's disease and non-Hodgkin's lymphoma and in the follow-up of dysgerminoma.

Hemolysis, if sufficiently severe, produces an LD isoenzyme pattern similar to that in myocardial infarction. Megaloblastic anemias, usually resulting from the deficiency of folate or vitamin B_{12}, cause the erythrocyte precursor cell to break down in the bone marrow (ineffective erythropoiesis), resulting in the release of large quantities of LD-1 and LD-2 isoenzymes. Marked elevations of the total LD activity in serum—up to 50 times the upper reference limit—have been observed in the megaloblastic anemias. These elevations rapidly return to normal after appropriate treatment.

Elevations of LD activity are observed in liver disease, but these elevations are not as great as the increases in aminotransferase activity. Elevations are especially high (10 times normal) in toxic hepatitis with jaundice. Slightly lower values are observed in viral hepatitis and in infectious mononucleosis, the latter often associated with elevations of LD-3. LD activity is normal or at most twice the upper reference limit in cirrhosis and obstructive jaundice. Serum LD-5 is often notably elevated in patients with either primary liver disease or liver anoxia secondary to decreased oxygen perfusion.

Patients with malignant disease show increased LD activity in serum; up to 70% of patients with liver metastases and 20% to 60% of patients with other nonhepatic metastases have elevated total LD activity. Notably elevated LD-1 is observed in germ cell tumors (61% of cases), such as teratoma, seminoma of the testis, and dysgerminoma of the ovary. Patients with seminoma have a raised LD-1 in 63% of cases compared with 60% in nonseminoma cases.[206] The percent of patients with increased LD-1 depended on the stage of the disease. LD-1 appeared to be a useful predictor of outcome in patients with testicular germ cell tumors.

In healthy subjects, cerebrospinal fluid (CSF)-LD activity is very much lower than the serum activity, and LD-4 and LD-5 are frequently undetectable. The pattern is also complicated by the possibility of contamination by hemorrhage or the disruption of the blood-brain barrier by disease, which adds LD of systemic origin to the CSF.[34] Additionally, LD isoenzymes may be released from cells that have infiltrated into the CSF. For example, in bacterial meningitis, the resulting granulocytosis produces an elevation of LD-4 and LD-5, whereas viral meningitis produces lymphocytosis, which may create an elevation of LD-1 through LD-3.

Methods for the Determination of Lactate Dehydrogenase Activity

Routine methods for both the forward ($L \rightarrow P$) and reverse ($P \rightarrow L$) reactions are available. However, within the last decade, there has been a significant move from the $P \rightarrow L$ to the $L \rightarrow P$ reaction. An $L \rightarrow P$ continuous-monitoring reference method, optimized for LD-1, has been developed by the IFCC Committee on Enzymes.[13] This method has recently been the basis for developing an IFCC reference procedure for LD at 37 °C.[176]

Serum is the preferred specimen for measuring LD activity. Plasma samples may be contaminated with platelets, which contain high concentrations of LD.[12] Serum should be separated from the clot as soon as possible after the specimen has been obtained. Hemolyzed serum must not be used because erythrocytes contain 150 times more LD activity (particularly LD-1 and LD-2) than serum. The different isoenzymes vary in their sensitivity to cold, LD-4 and LD-5 being especially labile. Activity of LD-4 and LD-5 is lost if the samples are stored at −20 °C. Thus serum specimens should be stored at room temperature, at which no loss of activity occurs for at least 3 days.

Reference Intervals

Values for LD activity in serum vary considerably, depending on the direction of the enzyme reaction and the method used. The reference interval in adult subjects, determined with the IFCC reference procedure at 37 °C, was found to be 125 to 220 U/L.[131] LD reference limits are higher in children (180 to 360 U/L).

Methods for the Separation and Quantification of Lactate Dehydrogenase Isoenzymes

Electrophoretic separation on agarose gels or cellulose acetate membranes is the procedure most commonly used to demonstrate LD isoenzymes.[117] After the isoenzymes have been separated by electrophoresis, a reaction mixture is layered over the separation medium. The mixture (typically D, L-lactate, 500 mmol/L, and NAD^+, 13 mmol/L, often dissolved in a suitable pH 8.0 buffer) is applied as a liquid or in a gel. The NADH generated over the LD zones is detected either by its fluorescence, when excited by long-wave ultraviolet light (365 nm), or by its reduction of a tetrazolium salt to form a colored formazan.

Using an agarose gel technique with fluorometric quantitation of the generated NADH, the following reference intervals for isoenzymes were obtained (expressed as percent of total LD): LD-1, 14% to 26%; LD-2, 29% to 39%; LD-3, 20% to 26%; LD-4, 8% to 16%; and LD-5, 6% to 16%.

Selective chemical inhibition methods have been described to inhibit serum LD-2 through LD-5, thus permit-

ting the assay of LD-1 alone. Chemicals used as inhibitors include 1,6-hexanediol, sodium perchlorate, and guanidine thiocyanate. An immunoprecipitation method using a goat antiserum against purified LD-5 has been used to measure LD-1. This antiserum binds LD isoenzymes LD-2 through LD-5. These bound isoenzymes are precipitated by the addition of a second antibody, leaving only LD-1 in the supernatant.

ALDOLASE

Aldolase (EC 4.1.2.13; D-fructose-1,6-bisdiphosphate D-glyceraldehyde-3-phosphate-lyase; ALD) catalyzes the splitting of D-fructose-1,6-diphosphate to D-glyceraldehyde-3-phosphate (GLAP) and dihydroxyacetone-phosphate (DAP), an important reaction in the glycolytic breakdown of glucose to lactate.

ALD is a tetramer with subunits determined by three separate gene loci. Only two of these loci, those producing A and B subunits, appear to be active simultaneously in most tissues, so the most common isoenzyme pattern consists of various proportions of the components of a five-member set of isoenzymes, of which two members correspond to the A and B homopolymers. The locus that determines the structure of the C subunit is active in brain tissue, as is the A locus, so this tissue contains ALD A and C together with the three corresponding heteropolymers.

Clinical Significance

Serum ALD determinations have been of some clinical interest in primary diseases of skeletal muscle. Some researchers believe that increased ALD activity is useful in distinguishing neuromuscular atrophies from myopathies in combination with the CK/AST ratio.[66] In general, however, measurement of ALD activity in serum does not add information to that available more readily from measurement of other enzymes, such as AST, LD, and especially CK. A recent study, assessing the utility of ALD determination by monitoring patient outcome, showed no clinical benefit when ALD was used in addition to CK in evaluating patients with suspected muscle disease.[62]

Methods for the Measurement of Aldolase Activity

All assay methods are based on the forward ALD-catalyzed reaction. Both photometric fixed-time and continuous-monitoring procedures have been developed. In the analytical approach on which all the commonly used procedures and kits are based, the ALD reaction is coupled with two other enzyme reactions. Triosephosphate isomerase (EC 5.3.1.1) is added to ensure rapid conversion of all GLAP to DAP. Glycerol-3-phosphate dehydrogenase (EC 1.1.1.8) is added to reduce the DAP to glycerol-3-phosphate, with NADH acting as hydrogen donor. The decrease in NADH concentration is then measured.[153]

The ALD activity in serum is quite stable. Activity is unchanged at ambient temperature for up to 48 hours and at 4 °C for several days. Hemolyzed specimens should not be used, and plasma is preferred over serum because of the possible release of platelet enzyme during the clotting process.

Reference Intervals

The reference interval for the activity of ALD in adults is 2.5 to 10 U/L, measured at 37 °C. However, there is a definite sex difference with men having higher values. Serum ALD in the neonate is fourfold the adult activity and in children is twice that of the adult. Adult values are attained by the time the child reaches puberty.[205]

GLYCOGEN PHOSPHORYLASE

Glycogen phosphorylase (EC 2.4.1.1; 1,4-alpha-D-glucan:orthophosphate alpha-D-glucosyltransferase; GP) plays an essential role in the regulation of carbohydrate metabolism by mobilizing glycogen. It catalyzes the first step in glycogenolysis in which glycogen is converted to glucose-1-phosphate. The physiological role of muscle GP is to provide the fuel for the energy supply required for muscle contraction. GP exists in the myocyte in association with glycogen and the sarcoplasmic reticulum, forming a macromolecular complex. The degree of association of GP with this complex depends on the metabolic state of the muscle. With the onset of tissue hypoxia, when glycogen is broken down and disappears, GP becomes soluble and can move from the peri-sarcoplasmic reticulum compartment directly into the extracellular fluid (Figure 21-2).

GP exists as a dimer composed of two identical subunits. Three GP isoenzymes are found in human tissues: GP-LL,

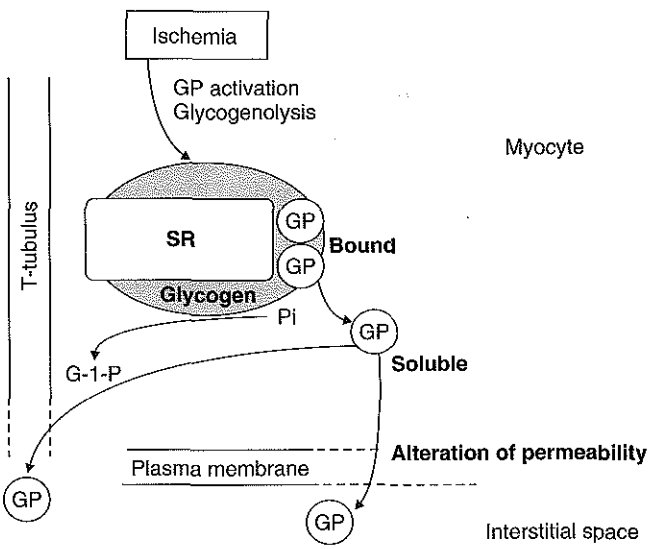

Figure 21-2 Release of glycogen phosphorylase (GP) from damaged muscle. GP and glycogen are tightly associated with the vesicles of sarcoplasmic reticulum (SR) under normal conditions. Ischemic injury is known to favor the conversion of bound GP into soluble GP, giving rise to the efflux of GP into the extracellular fluid. *Pi*, Inorganic phosphate; *G-1-P*, glucose-1-phosphate. *(Modified from Krause EG, Rabitzsch G, Noll F, Mair J, Puschendorf B. Glycogen phosphorylase isoenzyme BB in diagnosis of myocardial ischemic injury and infarction. Mol Cell Biochem 1996;160-1:289-95.)*

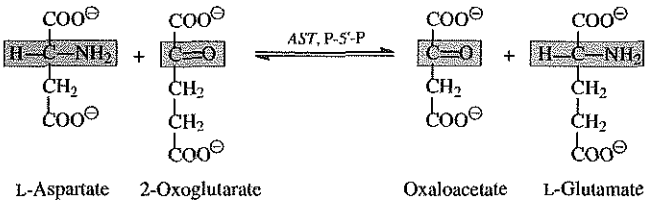
GP-MM, and GP-BB. Adult skeletal muscle contains only GP-MM. GP-LL is the predominant isoenzyme in liver and all other human tissues except for heart, skeletal muscle, and brain. GP-BB is the predominant isoenzyme in the human brain. In the heart, the isoenzymes BB and MM are found, but GP-BB is the predominant isoenzyme in the myocardium as well.

Clinical Significance[100]

In preliminary studies, GP-BB was significantly more sensitive than CK and CK-MB for AMI diagnosis during the first 3 to 4 hours after the onset of chest pain. Therefore GP-BB may be an important marker for the early diagnosis of AMI. Similar to other cytoplasmic proteins, such as myoglobin and CK-MB, the time course of GP-BB can be notably influenced by early reperfusion of the infarct-related coronary artery, with a more rapid increase and earlier peak. GP-BB is, however, not a heart-specific protein and its specificity as a marker for myocardial damage is limited.

Methods for the Measurement of Glycogen Phosphorylase Isoenzyme BB

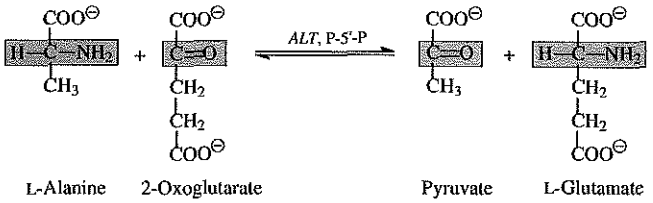
Methods were described for the estimation of GP activity in serum on the enzymic determination of glucose-1-phosphate in a coupled assay system and for the electrophoretic separation of GP isoenzymes.[88] More recently, an immunoenzymometric assay for the measurement of the isoenzyme GP-BB was developed.[157] The upper reference limit of this research assay was 7 μg/L.



LIVER ENZYMES

Enzymes in this category include alanine and aspartate aminotransferases, glutamate dehydrogenase (GLD), ALP, 5′-nucleotidase (NTP), γ-glutamyl transferase (GGT), glutathione S-transferase (GST), and serum cholinesterase (CHE). The aminotransferases and ALP are widely used. They have long been mistakenly called, as a group, "liver function tests." They are not, of course, but the habit persists. GGT is widely available in the United States and on automated analyzers. The others have not been adopted as widely.

Aminotransferases



The aminotransferases constitute a group of enzymes that catalyze the interconversion of amino acids to 2-oxo-acids by transfer of amino groups. Aspartate aminotransferase (EC 2.6.1.1; L-aspartate:2-oxoglutarate aminotransferase; AST) and alanine aminotransferase (EC 2.6.1.2; L-alanine:2-oxoglutarate aminotransferase; ALT) are examples of aminotransferases that are of clinical interest.

The 2-oxoglutarate/L-glutamate couple serves as one amino group acceptor and donor pair in all amino-transfer reactions; the specificity of the individual enzymes derives from the particular amino acid that serves as the other donor of an amino group. Thus AST catalyzes the reaction.

L-Aspartate 2-Oxoglutarate Oxaloacetate L-Glutamate

ALT catalyzes the analogous reaction.

L-Alanine 2-Oxoglutarate Pyruvate L-Glutamate

The reactions are reversible, but the equilibria of the AST and ALT reactions favor formation of aspartate and alanine, respectively.

Pyridoxal-5′-phosphate (P-5′-P) and its amino analogue, pyridoxamine-5′-phosphate, function as coenzymes in the amino-transfer reactions. The P-5′-P is bound to the apoenzyme and serves as a true prosthetic group. The P-5′-P bound to the apoenzyme accepts the amino group from the first substrate, aspartate or alanine, to form enzyme-bound pyridoxamine-5′-phosphate and the first reaction product, oxaloacetate or pyruvate, respectively. The coenzyme in amino form then transfers its amino group to the second substrate, 2-oxoglutarate, to form the second product, glutamate. P-5′-P is thus regenerated.

Both the coenzyme-deficient apoenzymes and the holoenzymes may be present in serum. Therefore, addition of P-5′-P under conditions that allow recombination with the enzymes usually produces an increase in aminotransferase activity. In accordance with the principle that all factors affecting the rate of reaction must be optimized and controlled, IFCC recommends addition of P-5′-P in aminotransferase methods to ensure that all the enzymatic activity is measured.

Transaminases are widely distributed throughout the body. AST is found primarily in the heart, liver, skeletal muscle, and kidney, whereas ALT is found primarily in the liver and kidney, with lesser amounts in heart and skeletal muscle (Table 21-2). ALT is exclusively cytoplasmic; both mitochondrial and cytoplasmic forms of AST are found in cells. These are genetically distinct isoenzymes with a dimeric structure composed of two identical polypeptide subunits of about 400 amino acid residues.[134]

Clinical Significance

Liver disease is the most important cause of increased transaminase activity in serum. In most types of liver disease, ALT activity is higher than that of AST; exceptions may be seen in alcoholic hepatitis, hepatic cirrhosis, and liver neoplasia. In viral hepatitis and other forms of liver disease associated with acute hepatic necrosis, serum AST and ALT

TABLE 21-2 Transaminase Activities in Human Tissues, Relative to Serum as Unity

	AST	ALT
Heart	7800	450
Liver	7100	2850
Skeletal muscle	5000	300
Kidneys	4500	1200
Pancreas	1400	130
Spleen	700	80
Lungs	500	45
Erythrocytes	15	7
Serum	1	1

From King J. Practical Clinical Enzymology. London: D Van Nostrand Co, Ltd, 1965.

concentrations are elevated even before the clinical signs and symptoms of disease (such as jaundice) appear. Activities for both enzymes may reach values as high as 100 times the upper reference limit, although tenfold to fortyfold elevations are most frequently encountered. Peak values of transaminase activity occur between the 7th and 12th days; activities then gradually decrease, reaching normal levels by the 3rd to 5th week if recovery is uneventful. Peak activities bear no relationship to prognosis and may fall with worsening of the patient's condition.

Persistence of increased ALT for more than 6 months after an episode of acute hepatitis is used to diagnose chronic hepatitis. Most patients with chronic hepatitis have maximum ALT less than seven times the upper reference limit. ALT may be persistently normal in 15% to 50% of patients with chronic hepatitis C, but the likelihood of continuously normal ALT decreases with an increasing number of measurements. In patients with acute hepatitis C, ALT should be measured periodically over the next 1 to 2 years to determine if it becomes and stays normal.[45]

The picture in toxic hepatitis is different from that in infectious hepatitis. In acetaminophen-induced hepatic injury, the transaminase peak is more than 85 times the upper reference limit in 90% of cases, a value rarely seen with acute viral hepatitis. Furthermore, AST and ALT activities typically peak early and fall rapidly.[45]

Nonalcoholic steatohepatitis is the most common cause of aminotransferase increases other than viral and alcoholic hepatitis. Increased transaminase concentrations have been observed in extrahepatic cholestasis, with activities tending to be higher the more chronic the obstruction. The aminotransferase activities observed in cirrhosis vary with the status of the cirrhotic process and range from the upper reference limit to four to five times higher, with an AST/ALT ratio greater than 1. The ratio's elevation can reflect the grade of fibrosis in these patients. This appears to be attributable to a reduction of ALT production in a damaged liver. Twofold to fivefold elevations of both enzymes occur in patients with primary or metastatic carcinoma of the liver, with AST usually being higher than ALT, but activities are often normal in the early stages of malignant infiltration of the liver. Slight or moderate elevations of both AST and ALT activities have been observed after administration of various medications, such as nonsteroidal antiinflammatory drugs, antibiotics, antiepileptic drugs, inhibitors of hydroxymethylglutaryl-coenzyme A reductase, or opiates. In patients with increased transaminases, negative viral markers, and a negative history for drugs or alcohol ingestion, the workup should include less common causes of chronic hepatic injury (i.e., hemochromatosis, Wilson's disease, autoimmune hepatitis, primary biliary cirrhosis, sclerosing cholangitis, and α_1-antitrypsin deficiency).[154]

Although serum activities of both AST and ALT become elevated whenever disease processes affect liver cell integrity, ALT is the more liver-specific enzyme. Serum elevations of ALT activity are rarely observed in conditions other than parenchymal liver disease. Moreover, elevations of ALT activity persist longer than do those of AST activity.

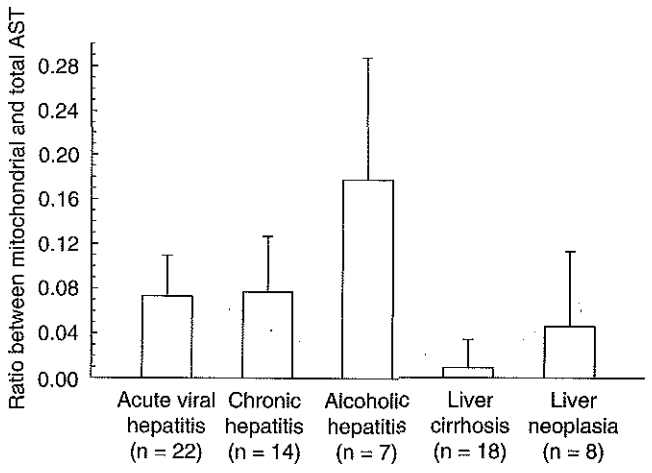
After AMI, increased AST activity appears in serum, as might be expected from the high AST concentration in heart muscle. AST activity also is increased in progressive muscular dystrophy and dermatomyositis, reaching concentrations up to eight times normal; they are usually normal in other types of muscle diseases, especially in those of neurogenic origin. If striated muscle is the source of increased AST activity, serum CK will be elevated contemporaneously. Pulmonary emboli can increase AST to two to three times normal, and slight to moderate elevations are noted in celiac sprue, acute pancreatitis, crushed muscle injuries, and hemolytic disease.

Generally, mitochondrial AST (m-AST) activity in serum shows a marked increase in patients with extensive liver cell degeneration and necrosis. Of particular interest is the usefulness of the ratio between m-AST and total AST activities for diagnosing alcoholic hepatitis. The ratio seems to clearly identify the liver-cell "necrotic type" condition (i.e., slight enzyme increase concomitant with relatively high activities of mitochondrial enzymes), typical of alcoholic hepatitis (Figure 21-3).[134]

Several authors have described AST linked to immunoglobulins, or macro-AST. The typical findings are a persistent increase of serum AST activity in an asymptomatic subject, with the absence of any demonstrable pathology in organs rich in AST. The increased AST activity might reflect decreased clearance of the abnormal complex from plasma. Macro-AST has no known clinical relevance. However, identification is important to avoid unnecessary diagnostic procedures in these subjects.[134]

Methods for the Measurement of Transaminase Activity

The assay system for measuring transaminase activity contains two amino acids and two oxo-acids. As there is no convenient method for assaying amino acids, formation or consumption of the oxo-acids is measured. Historically,



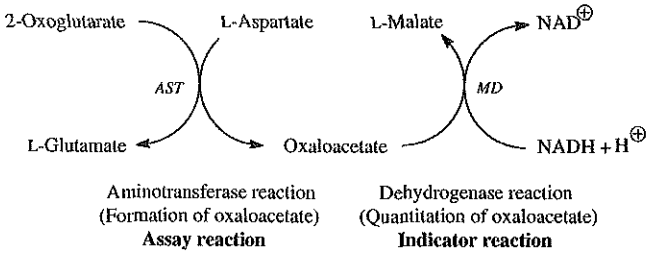


Figure 21-3 The ratio (mean ± SD) of mitochondrial to total AST in hepatic diseases. The difference between alcoholic hepatitis and other hepatic diseases is statistically significant ($p < 0.05$). *(Modified from Panteghini M, Falsetti F, Chiari E, Malchiodi A. Determination of aspartate aminotransferase isoenzymes in hepatic diseases. Lab J Res Lab Med 1983;10:515-9.)*

various photometric substrates (2,4-dinitrophenylhydrazine and various dyes) were coupled to the transaminase reactions. Methods based on these reactions are now considered obsolete. Today, continuous-monitoring methods are used to measure transaminase activity, by coupling the transaminase reactions to specific dehydrogenase reactions. The oxo-acids formed in the transaminase reaction are measured indirectly by enzymatic reduction to the corresponding hydroxy acids, the accompanying change in NADH concentration being monitored spectrophotometrically. Thus oxaloacetate, formed in the AST reaction, is reduced to malate in the presence of malate dehydrogenase (MD).

Pyruvate formed in the ALT reaction is reduced to lactate by LD. The substrate, NADH, and the auxiliary enzymes, MD or LD, must be present in sufficient quantity so that the reaction rate is limited only by the amounts of AST and ALT, respectively. As the reactions proceed, NADH is oxidized to NAD^+. The disappearance of NADH is followed by measuring the decrease in absorbance at 340 nm for several minutes, either continuously or at frequent intervals. The change in absorbance per minute (ΔA/min) is proportional to the micromoles of NADH oxidized and in turn to micromoles of substrate transformed per minute. A preliminary incubation period is necessary to ensure that NADH-dependent reduction of endogenous oxo-acids in the sample is completed before adding 2-oxoglutarate to start the transaminase reaction. After a brief lag phase, the change in absorbance (ΔA) is monitored. As already mentioned, supplementation with P-5′-P ensures that all the transaminase activity of the sample is measured.

AST activity in serum is stable for up to 48 hours at 4 °C. Specimens have to be stored frozen if they are to be kept longer. ALT activity should be assayed on the day of sample collection since activity is lost at room temperature, 4 °C, and −25 °C. ALT stability is better maintained at −70 °C. Hemolyzed specimens should not be used.

Standardization[145]

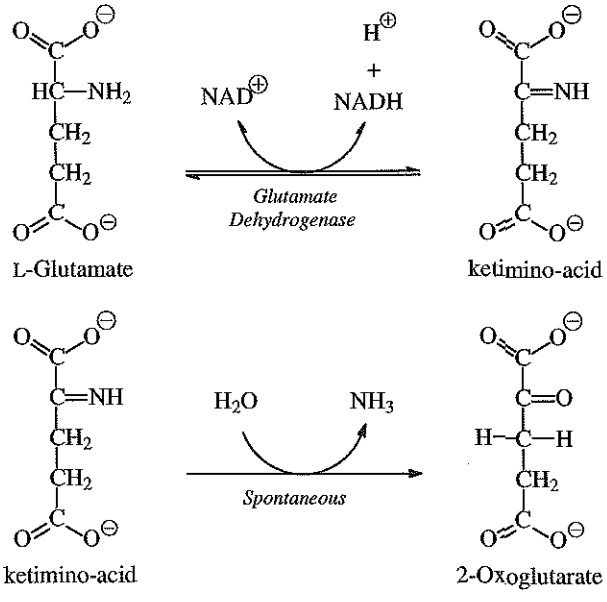
Because of the large numbers of AST and ALT activity measurements performed daily in clinical laboratories throughout the world and because of notable differences when results between laboratories are compared, standardization of transaminase measurements is a priority need for patient care. As discussed in Chapter 8, the reference system approach, based on the concepts of metrological traceability and of hierarchy of analytical measurement procedures, gives clinical laboratories and the medical community universal means of creating and ensuring the comparability of results. In this system, the IFCC reference measurement procedure forms the highest metrological level and thereby constitutes the definition of the respective measurable enzyme quantity. Primary IFCC procedures for the measurement of catalytic activity concentrations of AST and ALT at 37 °C have recently been redesigned and published.[178,179] Values assigned to the manufacturer's product calibrators and measurement results of lower metrological levels, including those in daily routine practice, should be traceable to these top-level reference measurement procedures, thus improving accuracy and comparability of transaminase results. It should be remembered that the concept of the reference system is valid only if the reference procedure and corresponding routine procedures have identical, or at least very similar, specificities for the measured enzyme. Thus it will not be possible to calibrate procedures for aminotransferases that do not incorporate P-5′-P using a procedure that does, such as the IFCC reference procedure, because the ratio of preformed holoenzyme to apoenzyme differs among specimens.

Reference Intervals[180]

When using the new IFCC methods, the AST upper reference limits for adults, calculated as the 97.5 percentile of the reference distribution, are 31 U/L for women and 35 U/L for men, respectively. The corresponding ALT upper reference limits are 34 U/L and 45 U/L.

Methods for the Separation and Quantification of AST Isoenzymes[134]

Several methods have been proposed to quantify AST isoenzymes in human serum. The most commonly used are electrophoresis, selective inhibition, and immunoassays. AST



isoenzymes can be separated into an anionic (cytoplasmic AST) and a cationic band (m-AST) by electrophoresis. However, the low concentration of m-AST in normal sera is usually below the limit of detection of this method. Rej described immunoprecipitation assays using antibodies directed against both purified mitochondrial and cytosolic isoenzymes. A similar assay, using anticytoplasmic AST antibody conjugated to sheep erythrocytes, became the basis for a diagnostic kit technique. As a rule, these assays allow direct measurement of low concentrations of the m-AST isoenzyme present in serum. More recently, there have been reports on the selective proteolysis of AST isoenzymes by several proteases. In particular, a homogeneous inhibition assay using proteinase K (EC 3.4.21.14) for selective proteolysis of cytosolic AST was described and made amenable to automation, permitting m-AST to be measured with convenience that approaches that of the total AST assay.[143]

About 5% to 10% of the activity of total AST in serum from healthy individuals is of mitochondrial origin. The upper reference limit for m-AST activity measured at 37 °C is 3.0 U/L.

Glutamate Dehydrogenase

Glutamate dehydrogenase (EC 1.4.1.3; L-glutamate: NAD(P) oxidoreductase, deaminating; GLD) is a mitochondrial enzyme found mainly in the liver, heart muscle, and kidneys, but small amounts occur in other tissue, including brain and skeletal muscle tissue, and in leukocytes.

GLD is a zinc-containing enzyme consisting of six polypeptide chains. The smallest active molecule has a molecular weight of about 350,000 kDa, but larger polymers are also found. The enzyme catalyzes the removal of hydrogen from L-glutamate to form the corresponding ketimino-acid that undergoes spontaneous hydrolysis to 2-oxoglutarate.

Although NAD^+ is the preferred coenzyme, $NADP^+$ also acts as the hydrogen acceptor. GLD is inhibited by metal ions, such as Ag^+ and Hg^+, by several chelating agents, and by L-thyroxine. The glutamate dehydrogenases of different human tissues may be separated by electrophoresis into several forms, probably resulting from different polymeric states.

Clinical Significance[174]

GLD is increased in serum of patients with hepatocellular damage. Fourfold or fivefold elevations are seen in chronic hepatitis; in cirrhosis, increases are only up to twofold. Very large rises in serum GLD occur in halothane toxicity, and notable increases occur in response to some other hepatotoxic agents.

GLD potentially offers differential diagnostic potential in the investigation of liver disease, particularly when interpreted in conjunction with other enzyme test results. The key to this differential diagnostic potential is to be found in the intraorgan and intracellular distribution of the enzyme. As an exclusively mitochondrial isoenzyme, GLD is released from necrotic cells; therefore, when compared with hepatic disorders with extensive necrosis, release is less in diffuse inflammatory processes, and in these conditions, the release of cytoplasmic enzymes, such as ALT, is quantitatively more pronounced. Together with m-AST, GLD is of value in estimation of the severity of liver cell damage.

GLD is more concentrated in the central areas of the liver lobules than in the periportal zones. This pattern of distribution is the reverse of that of ALT. Pronounced release of GLD is therefore to be expected in conditions in which centrilobular necrosis occurs (e.g., as a result of ischemia or in halothane toxicity).

Methods for the Determination of Glutamate Dehydrogenase Activity

Continuous-monitoring methods have been developed for the determination of GLD using both the forward and reverse reactions. The equilibrium favors the formation of glutamate, and higher reaction rates are observed when 2-oxoglutarate is used as a substrate. Serum is added to a solution of NADH, an ammonium salt, and ADP in buffer at pH 7.5, and the reaction is initiated by the addition of the substrate, 2-oxoglutarate. The rate of decrease in absorbance at 340 nm is measured. The German Society for Clinical Chemistry has published optimum reaction conditions for 37 °C.[42] Oxamate is incorporated into the reaction mixture because this acid inhibits LD activity, avoiding the critical consumption of NADH by this enzyme in serum.

GLD activity in serum is stable at 4 °C for 48 hours and at −20 °C for several weeks.

Reference Intervals

The GLD upper reference limits are 6 U/L (women) and 8 U/L (men), when a method optimized at 37 °C is used.

Alkaline Phosphatase

Alkaline phosphatase (EC 3.1.3.1; orthophosphoric-monoester phosphohydrolase [alkaline optimum]; ALP) cat-

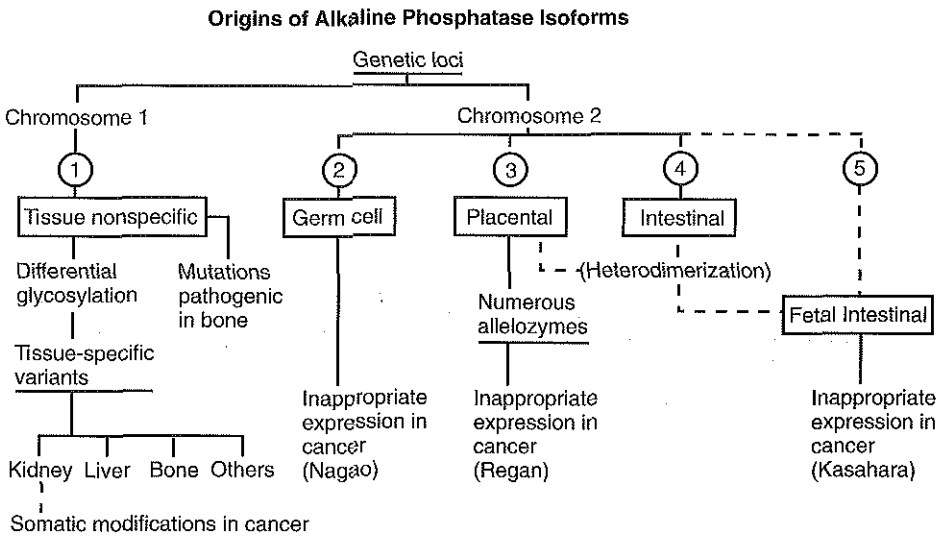


Figure 21-4 Identities, chromosomal assignments, and main physiological and pathological expression of genes encoding human alkaline phosphatases. *Broken lines* show two alternative proposed origins of the fetal intestinal alkaline phosphatase. The sequence of a cDNA is reportedly identical to that of adult intestinal AP. All the isoenzymes and isoforms are glycoproteins, imposing a further level of microheterogeneity. Different processes of cleavage or preservation of the membrane-anchoring domain can generate additional isoforms. *(Modified from Moss DW. Perspectives in alkaline phosphatase research. Clin Chem 1992;38:2486-92.)*

alyzes the alkaline hydrolysis of a large variety of naturally occurring and synthetic substrates.

ALP activity is present in most organs of the body and is especially associated with membranes and cell surfaces located in the mucosa of the small intestine and proximal convoluted tubules of the kidney, in bone (osteoblasts), liver, and placenta. Although the precise metabolic function of the enzyme is not yet understood, it appears that ALP is associated with lipid transport in the intestine and with the calcification process in bone.

ALP exists in multiple forms, some of which are true isoenzymes, encoded at separate genetic loci (Figure 21-4).[120] The bone, liver, and kidney ALP forms share a common primary structure coded for by the same genetic locus, but they differ in carbohydrate content.[118]

Some divalent ions, such as Mg^{2+}, Co^{2+}, and Mn^{2+}, are activators of the enzyme, and Zn^{2+} is a constituent metal ion. The correct ratio of Mg^{2+}/Zn^{2+} ions is necessary to avoid displacement of Mg^{2+} and to obtain optimal activity. Phosphate, borate, oxalate, and cyanide ions are inhibitors of ALP activity. Variations in Mg^{2+} and substrate concentrations change the pH optimum. The type of buffer present (except at low concentrations) affects the rate of enzyme activity. Buffers can be classified as inert (carbonate and barbital), inhibiting (glycine and propylamine), or activating (2-amino-2-methyl-1-propanol [AMP], tris (hydroxymethyl) aminomethane [TRIS], and diethanolamine [DEA]).

The ALP activity present in the sera of healthy adults originates mainly in the liver, with up to half the total activity coming from the skeleton. The respective contributions of these two forms to the total activity are age dependent. A small amount of intestinal ALP may also be present, particularly in the sera of individuals of blood group B or O, i.e., who are secretors of blood group substances. Tissue nonspecific ALP in serum is rapidly denatured at 56 °C but is relatively stable at lower temperatures.

Clinical Significance

Elevations in serum ALP activity commonly originate from one or both of two sources: the liver and bone. Consequently, serum ALP measurements are of particular interest in the investigation of two groups of conditions: hepatobiliary disease and bone disease associated with increased osteoblastic activity (see Bone Enzymes section later in this chapter).

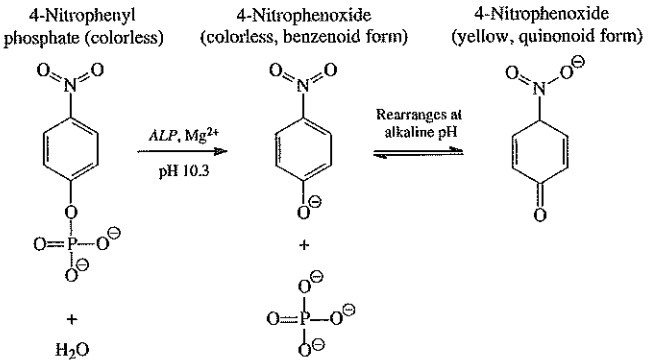
The response of the liver to any form of biliary tree obstruction induces the synthesis of ALP by hepatocytes. Some of the newly formed enzyme enters the circulation to increase the enzyme activity in serum.[121] The elevation tends to be more notable (greater than threefold) in extrahepatic obstruction (e.g., by stone or by cancer of the head of the pancreas) than in intrahepatic obstruction and is greater the more complete the obstruction. Serum enzyme activities may reach 10 to 12 times the upper reference limit and usually return to normal on surgical removal of the obstruction. A similar increase is seen in patients with advanced primary liver cancer or widespread secondary hepatic metastases. Liver diseases that principally affect parenchymal cells, such as infectious hepatitis, typically show only moderately (less than threefold) increased or even normal serum ALP activities (Table 21-3).[139] Increases may also be seen as a consequence of a reaction to drug therapy. Intestinal ALP

TABLE 21-3 Serum Alkaline Phosphatase Activities in Hepatobiliary Diseases

Disorder	No. of Patients	% of Patients With Abnormal ALP	Mean ALP Activity (Multiples of Upper Reference Limit)
Primary and metastatic liver neoplasia	25	92	4.15
Extrahepatic biliary obstruction	19	95	3.98
Acute viral hepatitis	33	79	2.36
Liver cirrhosis	34	76	1.18
Alcoholic hepatitis	33	76	1.13
Chronic hepatitis	14	78	1.03

From Panteghini M. Hepatic alkaline phosphatase isoenzyme: II. Clinical aspects. Giorn It Chim Clin 1990;15:301-8.

isoenzyme, an asialoglycoprotein normally cleared by the hepatic asialoglycoprotein receptors, is often elevated in patients with liver cirrhosis.



An increase of up to two to three times normal has been observed in women in the third trimester of pregnancy, with the additional enzyme being of placental origin. There are also reports of a benign familial elevation in serum ALP activity because of increased concentrations of intestinal ALP.[135] Transient, benign increases in serum ALP may be observed in infants and children, with changes often more than 10 times the upper reference limit. Increases in both the liver and the bone form are seen. These changes seem to reflect a reduction in the removal of ALP from blood caused by transient modifications of enzyme glycosylation.[187]

A result of the application of the techniques of isoenzyme analysis to the characterization of ALP in serum was the discovery that forms of the enzyme essentially identical with the normal placental isoenzyme appear in the sera of some patients with malignant diseases. These carcinoplacental isoenzymes (e.g., Regan isoenzyme) appear to result from the derepression of the placental ALP gene. As described below, the presence of these isoenzymes can be readily detected in serum by their stability at 65 °C. Tumors have also been found to produce ALPs that appear to be modified forms of nonplacental isoenzymes (Kasahara isoenzyme).

Methods for the Determination of Alkaline Phosphatase Activity

Numerous methods have been developed for determining ALP activity. In general, methodological developments have been directed at increasing the speed and sensitivity of the assay by selecting readily hydrolyzed substrates and phosphate-accepting buffers and toward the use of continuous-monitoring methods based on "self-indicating" substrates.

The most popular of the chromogenic or self-indicating substrates for ALP is 4-nitrophenyl phosphate (usually abbreviated 4-NPP or PNPP from the older name, *p*-nitrophenyl phosphate). This ester is colorless, but the final product is yellow at the pH of the reaction:

The enzyme reaction is continuously monitored by observing the rate of formation of the 4-nitrophenoxide ions. With improvements in the reaction conditions, this reaction forms the basis of current recommended and standard methods of ALP assay. Other self-indicating substrates include phenolphthalein monophosphate, thymolphthalein phosphate, and α-naphthyl phosphate. In the ALP methods discussed, the liberated phosphate group is transferred to water. The rate of phosphatase action is enhanced, however, if certain amino alcohols are used as phosphate-accepting buffers. Among these activators are compounds such as AMP, DEA, TRIS, ethylaminoethanol (EAE), and *N*-methyl-d-glucamine (MEG). Enzyme activity in the presence of optimal concentrations of these buffers is twofold to sixfold greater than in the presence of a nonactivating buffer, such as carbonate.

ALP catalyzes the hydrolysis of 4-NPP, forming phosphate and free 4-nitrophenol (4-NP, PNP), which in dilute acid solutions is colorless. Under alkaline conditions, 4-NP is converted to the 4-nitrophenoxide ion, which has a very intense yellow color. The rate of formation of 4-NP by the action of the enzyme on 4-NPP at 37 °C is then monitored at 405 nm with a recording spectrophotometer. The (provisional) IFCC-recommended method uses 4-NPP as the substrate and AMP as the phosphate-acceptor buffer. It

includes Mg^{2+} and Zn^{2+}, optimal concentrations of which are controlled by the addition of Mg^{2+} and Zn^{2+}, and the chelating agent *N*-hydroxyethylethylenediaminetriacetic acid (HEDTA). Although Zn^{2+} ions are present in a total concentration of 1 mmol/L, most are bound to HEDTA, leaving only a small, experimentally determined optimal concentration of free ions. A similar situation exists for Mg^{2+} ions. Thus HEDTA acts as a metal ion buffer, maintaining optimal concentrations of the two ions.[195]

Serum or heparinized plasma, free of hemolysis, should be used. Complexing anticoagulants—such as citrate, oxalate, and EDTA—must be avoided, because they bind cations, such as Mg^{2+} and Zn^{2+}, which are necessary cofactors for ALP activity measurement. Blood transfusion (containing citrate) causes a transient decrease in serum ALP through a similar mechanism. Freshly collected serum samples should be kept at room temperature and assayed as soon as possible but preferably within 4 hours after collection. In sera stored at a refrigerated temperature, ALP activity increases slowly (2%/d). Frozen specimens should be thawed and kept at room temperature for 18 to 24 hours before measurement to achieve full enzyme reactivation.

Reference Intervals[148,197]

ALP activities in serum vary with age. Children show higher ALP activity than healthy adults as a result of the leakage of bone ALP from osteoblasts during bone growth. Using the IFCC procedure at 37 °C, the following reference intervals (central 95 percentiles) have been established:

Sex	Age	Reference Interval
Males-females	4-15 yr	54-369 U/L
Males	20-50 yr	53-128 U/L
	≥60 yr	56-119 U/L
Females	20-50 yr	42-98 U/L
	≥60 yr	53-141 U/L

Activities in growing children are highly variable.

Methods for the Separation and Quantification of Alkaline Phosphatase Isoenzymes

Assays for ALP isoenzymes are needed when: (1) the source of an elevated ALP in serum is not obvious and should be clarified; (2) the main clinical question is concerned with detecting the presence of liver or bone involvement; and (3) in the case of metabolic bone disorders, to ascertain any modifications in the activity of osteoblasts to monitor the disease activity and the effect of appropriate therapies.

Criteria that have been used to differentiate the isoenzymes and other multiple forms of ALP include: (1) electrophoretic mobility; (2) stability to denaturation by heat or chemicals; (3) response to the presence of selected inhibitors; (4) affinity for specific lectins; and (5) immunochemical characteristics.[156]

The same electrophoretic techniques are used for the separation of ALP isoenzymes in serum as for separations of serum proteins. After electrophoresis, ALP zones are made visible by incubating the gel in a solution of buffered substrate (e.g., 1-naphthyl phosphate, to which a chromogenic system, usually represented by a diazonium salt, is added; in the case of electrophoresis on cellulose acetate, the strips are covered with an agar-gel layer containing the staining system). The liver ALP typically moves most rapidly toward the anode. Bone ALP, which typically gives a more diffuse zone than the liver form, has a slightly lower anodal mobility, although the two zones usually overlap to some extent. Intestinal ALP migrates more slowly than the bone enzyme, whereas the placental isoenzyme commonly appears as a discrete band overlying the diffuse bone fraction. An additional band, which is frequently present in the serum of patients with various hepatic diseases, contains a high molecular weight form of ALP but is also strongly negatively charged. Therefore it moves slowly in starch gel or may even fail to enter polyacrylamide gel, but it migrates more anodally than the main liver zone on nonsieving media, such as cellulose acetate. Investigations on this form have revealed that it corresponds to the main liver form attached to the membrane moiety (*membrane particle [fragment] ALP*).[138]

Complexes between ALP and immunoglobulins, or macro-ALP, occur occasionally in serum, giving rise to abnormally migrating bands in the γ-globulin zone; however, these do not provide specific diagnostic information in the present state of knowledge.

Two approaches have been proposed to improve the electrophoretic separation between bone and liver ALPs. Both methods exploit differences in the carbohydrate portions of the two forms of ALP. In one, electrophoresis is carried out in the presence of wheat germ lectin, which retards bone ALP migration more than the liver enzyme migration.[170] In the other, serum is treated briefly (i.e., for 15 min at 37 °C), with neuraminidase to remove part of the terminal sialic acid residues. As the sialic acid residues of bone ALP are more readily attacked than those of liver ALP, the electrophoretic mobility of the bone form is reduced more than that of liver ALP. The improved separation allows quantitative estimates to be made by densitometric scanning (Figure 21-5).[122]

Overnight incubation of the serum sample with neuraminidase also is used to confirm the presence of intestinal ALP. This treatment reduces the anodal mobility of all ALP isoenzymes except that of intestinal origin, which is neuraminidase-resistant because terminal sialic acid residues are not present in the molecule.

Because placental ALP is heat stable, incubation of the serum sample at a temperature as high as 65 °C for 30 minutes provides a convenient test for the presence of this isoenzyme. Other forms of ALP can also be differentiated based on their stability at high temperature. At 56 °C, for example, liver ALP is more stable than the bone ALP. ("Bone burns.") Thus if after 10 minutes at 56 °C, less than 20% of the serum ALP activity remains, the enzyme present is probably largely of bone type. Residual activities of between

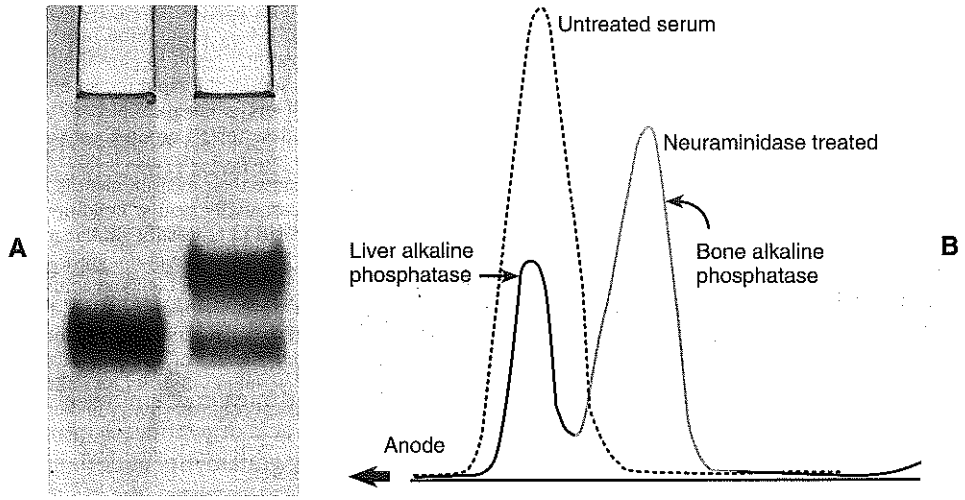


Figure 21-5 A, Polyacrylamide-gel electrophoresis of bone and liver alkaline phosphatases in human serum. *Left,* Mixture of two sera containing, respectively, entirely bone phosphatase and entirely liver phosphatase. *Right,* Mixture of the same two sera after each has been treated with neuraminidase for 10 minutes at 37 °C. The anodal direction is downward. The more anodal zone is liver phosphatase. **B,** Densitometric scans of electrophoretic patterns shown in A. *Broken line,* Scan of mixture of untreated sera; *solid line,* scan of mixture of sera treated briefly with neuraminidase. Clin Chim Acta 1984;143:177-82.)*

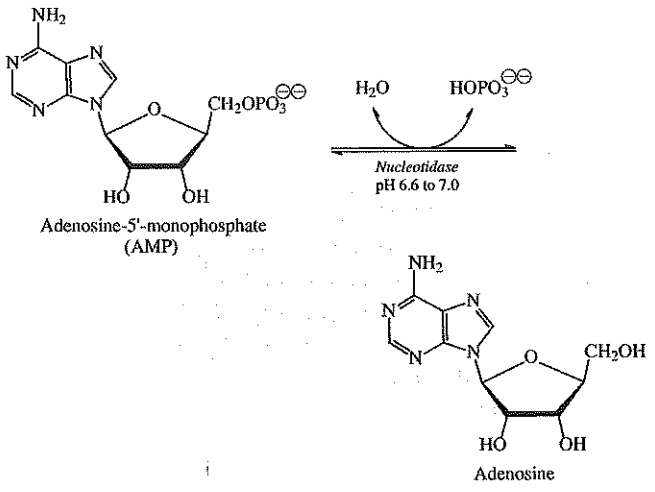


25% and 55% support electrophoretic evidence that liver ALP is the predominant form. The imprecision of the test reflects difficulties in standardizing the rate of sample heating (related to such things as the type of apparatus used to heat the serum sample, thermal conductivity of the sample container, and the volume of sample in the container during heating), the rate of sample cooling (e.g., in an ice bath), and the fact that the result (as a ratio or percent) includes uncertainties from two measurements. As an alternative to heat fractionation of ALP, measurement of GGT, which is increased in liver disease but not in bone disease, may be a useful rapid tool to distinguish between the two diseases as the explanation for an increased serum ALP. As discussed below, the pattern of increases of serum glutamyl transferase in liver diseases is similar to that for alkaline phosphatase.

The use of wheat germ lectin, binding the *N*-acetylglucosamine residues present in different amounts on individual isoenzymes, has also been the basis of a commercial technique for the selective precipitation and measurement of bone ALP. However, this technique does not provide sufficient accuracy and precision for quantifying the bone fraction.[112]

Immunological methods with polyclonal antisera or monoclonal antibodies provide the best quantitative measurements of intestinal or placental ALPs. Much more difficult is the production of antibodies that selectively react with different products of the tissue-nonspecific ALP gene, including the liver- and bone-derived isoforms, as these antibodies should recognize specific sugar side chains instead of a particular amino acid sequence. Until now, no monoclonal antibodies fully discriminate between liver and bone ALPs. Despite lack of complete specificity, the commercially available immunoassays of bone ALP may offer some advantages, but their value has not been convincingly demonstrated, in part because measurements of total ALP provide the required clinical information in many situations.

5′-Nucleotidase

5′-Nucleotidase (EC 3.1.3.5; 5′-ribonucleotide phosphohydrolase; NTP) is a phosphatase that acts only on nucleoside-5′-phosphates, such as adenosine-5′-phosphate (AMP) and adenylic acid, releasing inorganic phosphate.

NTP is a glycoprotein widely distributed throughout the tissues of the body and is principally localized in the cytoplasmic membrane of the cells in which it occurs. Its pH optimum is between 6.6 and 7.0.[188]

Clinical Significance

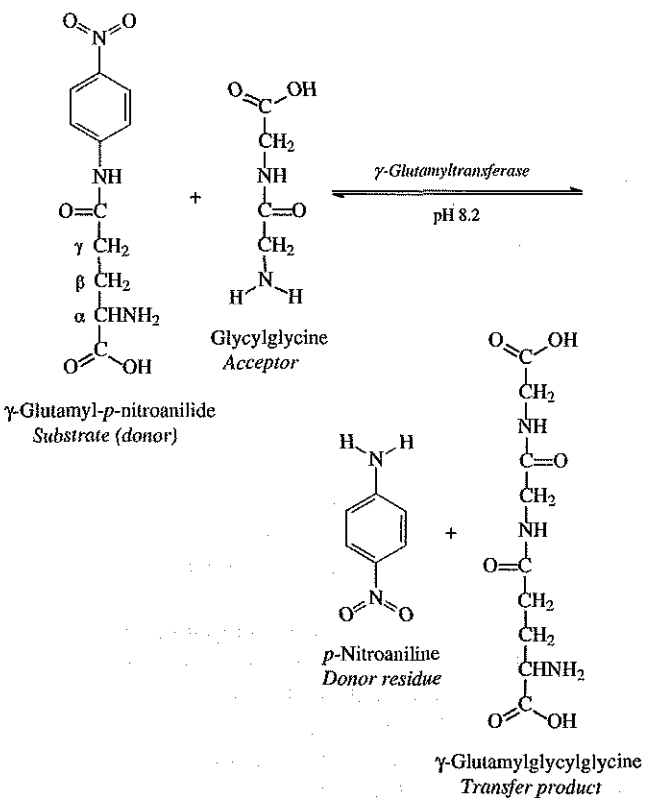
Despite its ubiquitous distribution, serum NTP activities appear to reflect hepatobiliary disease with considerable specificity. NTP is increased threefold to sixfold in those hepatobiliary diseases in which there is interference with the secretion of the bile. This may be due to extrahepatic causes (a stone or tumor occluding the bile duct), or it may arise from intrahepatic conditions, such as cholestasis caused by chlorpromazine, malignant infiltration of the liver, or biliary cirrhosis. When parenchymal cell damage is predominant, as in infectious hepatitis, serum NTP activity is only moderately elevated.

Assay of NTP activity has been considered of value as an addition to measurement of nonspecific total ALP in patients with suspected hepatobiliary disease, and abnormal NTP activity is routinely interpreted as evidence of a hepatic origin of increased ALP activity in serum. However, approximately half of individuals in whom liver ALP activity is increased in serum may simultaneously show a normal NTP. On the other hand, increased NTP in the serum of patients with normal liver ALP is very often associated with the presence of liver disease. Thus the frequent dissociation of the two enzyme activities supports the utility of determining both (liver) ALP and NTP to increase the diagnostic efficiency for diseases of the liver.[132]

Methods for the Determination of 5′-Nucleotidase Activity

The substrates most generally used in measuring the activity of NTP are AMP or IMP (inosine-5′-phosphate). However, these substrates are organic phosphate esters and thus can be hydrolyzed to an appreciable degree by other nonspecific (alkaline) phosphatases, even at a pH as low as 7.5, which is the pH assumed optimal for NTP activity. Methods for the estimation of NTP in serum must therefore incorporate some means for correcting for the hydrolysis of the substrate by the nonspecific phosphatases.

In a commercially available assay, serum NTP catalyzes the hydrolysis of IMP to yield inosine, which is then converted to hypoxanthine by purine-nucleoside phosphorylase (EC 2.4.2.1). Hypoxanthine is oxidized to urate with xanthine oxidase (EC 1.2.3.2). Two moles of hydrogen peroxide are produced for each mole of hypoxanthine liberated and converted to uric acid. The formation rate of hydrogen peroxide is monitored by a spectrophotometer at 510 nm by the oxidation of a chromogenic system. The effect of ALPs on IMP is inhibited by β-glycerophosphate. This material is substrate for ALP but not for NTP, and by forming substrate complexes with the former enzyme, it reduces the proportion of the total ALP activity that is directed to the hydrolysis of the NTP substrate, IMP.[19]



NTP activity in serum or plasma heparin is stable for at least 4 days at 4 °C and 4 months at −20 °C.

Reference Interval

The reference interval for NTP activity at 37 °C is from 3 to 9 U/L, with no sex-related differences.

Gamma-Glutamyl Transferase

Peptidases are enzymes that catalyze the hydrolytic cleavage of peptides to form amino acids or smaller peptides. They constitute a broad group of enzymes of varied specificity, and some individual enzymes act as amino acid transferases and catalyze the transfer of amino acids from one peptide to another amino acid or peptide. Gamma-glutamyl transferase (EC 2.3.2.2; γ-glutamyl-peptide:amino acid γ-glutamyltransferase; GGT) catalyzes the transfer of the γ-glutamyl group from peptides and compounds that contain it to some acceptor.[55] The γ-glutamyl acceptor is the substrate itself, some amino acid or peptide, or even water, in which case simple hydrolysis takes place. The enzyme acts only on peptides or peptidelike compounds containing a terminal glutamate residue joined to the remainder of the compound through the terminal (-γ-) carboxyl. Glycylglycine is five times more effective as an acceptor than is either glycine or the tripeptide (gly-gly-gly) but little is known about the optimal properties of the acceptor co-substrate. The peptidase transfer reaction is considerably faster than that of the simple hydrolysis reaction. An example of a reaction catalyzed by the enzyme is:

GGT is present (in decreasing order of abundance) in proximal renal tubule, liver, pancreas, and intestine. The enzyme is present in cytoplasm (microsomes), but the larger fraction is located in the cell membrane and may transport amino acids and peptides into the cell across the cell membrane in the form of γ-glutamyl peptides. It may also be involved in some aspects of glutathione metabolism.[214]

GGT activity in serum comes primarily from liver. The enzyme in serum is heterogeneous with respect to both net molecular charge (e.g., shown by electrophoresis) and size. These forms appear to derive from posttranslational modifications of a single type of enzyme molecule rather than to be due to the existence of true isoenzymes. For example, high molecular weight forms may represent the release of cell membrane fragments into the circulation. Despite numerous investigations, clear correlations between patterns of multiple forms and particular diseases cannot be discerned.

Clinical Significance

Even though renal tissue has the highest concentration of GGT, the enzyme present in serum appears to originate primarily from the hepatobiliary system. GGT is a sensitive indicator of the presence of hepatobiliary disease, being elevated in most subjects with liver disease regardless of cause, but its usefulness is limited by the lack of specificity. Like ALP, it is highest in cases of intrahepatic or posthepatic biliary obstruction, reaching activities some 5 to 30 times upper reference limit. High elevations of GGT are also observed in patients with either primary or secondary (metastatic) liver neoplasms; in these conditions, changes may occur earlier and are more pronounced than those with the other liver enzymes are. Moderate elevations (two to five times normal) occur in infectious hepatitis. Patients with chronic hepatitis C infection and high pretreatment serum GGT are unlikely to have a sustained virological response to interferon treatment. Small increases of GGT activity are observed in patients with fatty livers, and similar but transient increases are noted in cases of drug intoxication. In acute and chronic pancreatitis and in some pancreatic malignancies (especially if associated with hepatobiliary obstruction), enzyme activity may be 5 to 15 times the upper reference limit.

Elevated activities of GGT are found in the sera of patients with alcoholic hepatitis and in the majority of sera from people who are heavy drinkers. Increased concentrations of the enzyme are also found in serum of subjects receiving anticonvulsivant drugs such as phenytoin and phenobarbital. Such an increase of GGT activity in serum may reflect induction of new enzyme activity by the action of the alcohol and drugs and/or their toxic effects on microsomal structures in liver cells.

In AMI, GGT activity is usually normal. If there is a rise, it occurs at about the fourth day, reaches a maximum value in another 4 days, and probably implies liver damage secondary to cardiac insufficiency.

Unlike ALP, GGT is not increased in conditions in which osteoblastic activity is increased.

Methods for the Determination of γ-Glutamyltransferase Activity

Early GGT assays used L-γ-glutamyl-*p*-nitroanilide (GGPNA) as the substrate, with glycylglycine serving as the γ-glutamyl residue acceptor. However, GGPNA has limited solubility in the reaction mixture, and it is therefore difficult to obtain saturating substrate concentrations. The *p*-nitroaniline produced in the reaction is determined by its yellow color, which is monitored at 405 nm.

Derivatives of GGPNA are also available and have been used in other methods. In these derivatives, various groups have been introduced into the benzene ring to increase solubility in water. The most useful of these substrates is L-γ-glutamyl-3-carboxy-4-nitroanilide is readily soluble in water and is split by GGT at a rate comparable to that observed with GGPNA. Activities in serum are higher with the carboxyl derivative than with the noncarboxylated substrate, partly because of the higher substrate concentrations attainable with the former.

In the IFCC reference measurement procedure for GGT, L-γ-glutamyl-3-carboxy-4-nitroanilide serves as the substrate, with glycylglycine serving as an acceptor. Buffering is provided by glycylglycine itself. The temperature of reaction is 37 °C and the wavelength of measurement of the reaction product, 5-amino-2-nitrobenzoate, is 410 nm.[177]

GGT is a comparatively stable enzyme in vitro. Activity is stable for at least 1 month at 4 °C and 1 year at −20 °C. Nonhemolyzed serum is the preferred specimen, but EDTA plasma has also been used. Heparin may produce turbidity in the reaction mixture; citrate, oxalate, and fluoride depress GGT activity by 10% to 15%.

Reference Intervals

In adults, the upper reference limit for GGT activity in serum is 38 U/L for females and 55 U/L for males.[180] Reference limits are approximately twofold higher in people of African ancestry. In normal full-term neonates, the GGT activity at birth is approximately six to seven times the adult reference range. The activity then declines, reaching adult values by the age of 5 to 7 months.[33]

Glutathione S-Transferase

Cytosolic glutathione S-transferases (EC 2.5.1.18; GST) are dimeric enzymes that catalyze the nucleophilic addition of glutathione to the electrophilic centers of a wide variety of chemical structures, accomplishing detoxification reactions. In addition, GSTs exert part of the glutathione peroxidase activity and have an important function in intracellular binding and transport of a wide variety of both endogenous and exogenous compounds. The family of human enzymes is divided into four main classes: α, μ, π, and θ.[63]

α-GST is found at high concentrations in the human liver and is released quickly and in large quantities from damaged hepatocytes into the bloodstream.

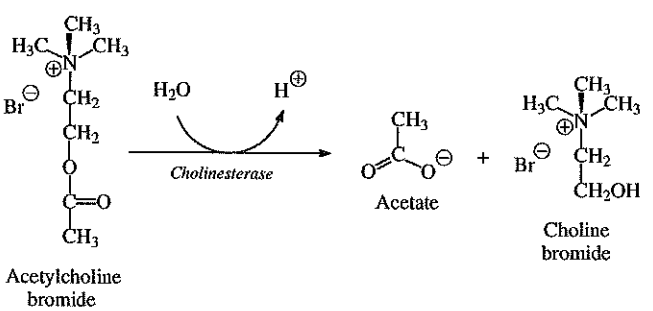
Clinical Significance

α-GST is an emerging marker for assessing hepatocellular damage. Unlike aminotransferases, which are found predominantly in the periportal hepatocytes, α-GST is evenly distributed across the liver acinus and is therefore released in all types of hepatocyte injury. In liver transplant recipients, α-GST was found more valuable than AST in detecting early rejection episodes postoperatively and less susceptible to the confounding effects of infection.

Methods for the Determination of Glutathione S-Transferase

Several problems have been associated with GST activity measurements. First, normal plasma activity is low and hard to measure. Secondly, GST binds a number of anions, such as bile salts and bilirubin, that inhibit enzyme activity. Immunoassays have been described that allow the precise and specific measurement of α-GST concentrations. At present, the only methodological problem relates to the speed of the assays, which take several hours.

Reference Interval



Using a commercially available enzyme immunoassay for α-GST, the upper reference limit was 11.4 μg/L.[164]

CHOLINESTERASE

Two related enzymes have the ability to hydrolyze acetylcholine. One is acetylcholinesterase (EC 3.1.1.7, acetylcholine acetylhydrolase), which is called true cholinesterase or choline esterase I. True cholinesterase is found in erythrocytes, the lungs and spleen, nerve endings, and the gray matter of the brain. It is responsible for the prompt hydrolysis of acetylcholine released at the nerve endings to mediate transmission of the neural impulse across the synapse. The degradation of acetylcholine is required for the depolarization of the nerve so that it is repolarized in the next conduction event.

The other cholinesterase is acylcholine acylhydrolase (EC 3.1.1.8, acylcholine acylhydrolase, CHE); it is also called pseudocholinesterase, serum cholinesterase, butyrylcholinesterase, or choline esterase II. Although it is found in the liver, pancreas, heart, white matter of the brain, and serum, its biological role is unknown. The assay of this enzyme is clinically useful.

The type of reaction catalyzed by both cholinesterases is:

The two enzymes differ in specificity toward some substrates while behaving similarly toward others. The serum enzyme acts on benzoylcholine but cannot hydrolyze acetyl-β-methylcholine; the red cell enzyme acts on the latter but not on the former. The red cell enzyme splits only choline esters; aryl or alkyl esters are not attacked. The red cell enzyme is inhibited by its substrate, acetylcholine, if present at about 10^{-2} mol/L; the serum enzyme is not inhibited by this substrate.

Both enzymes are inhibited by the alkaloids prostigmine and physostigmine, both of which contain quaternary nitrogen (present in choline) in their structures. These two compounds are typical competitive inhibitors, competing with the choline residue of acetylcholine for its binding site on the enzyme surface. Some organic phosphorus compounds, such as diisopropyl fluorophosphate, irreversibly inhibit both enzymes. The phosphoryl group binds very tightly to the enzyme site at which binding of the acyl group normally occurs, thus preventing attachment of the acetylcholine. Both enzymes are also inhibited by a large variety of other compounds, including morphine, quinine, tertiary amines, phenothiazines, pyrophosphate, bile salts, citrate, fluoride, and borate.

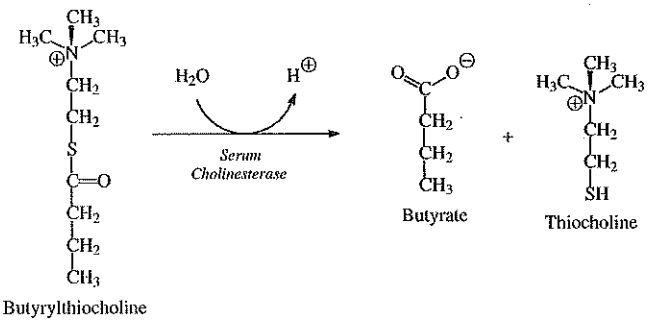
The CHE in normal sera is separated by electrophoresis into 7 to 12 bands, the number depending on the experimental technique used. The forms of CHE differ in molecular size and appear to be aggregates of different numbers of the same basic unit. Of more interest are the atypical (genetic) variants of the enzyme, characterized by diminished activity against acetylcholine and other substrates, which are found in the sera of a small fraction of apparently healthy people.

The gene controlling the synthesis of CHE can exist in many allelic forms. Four of the most common forms are designated as E^u, E^a, E^f, and E^s. These four allelic genes can be combined to form one normal and nine abnormal genotypes. At least 40 other forms exist and another gene locus is recognized (E_2). The normal, most common phenotype is designated as EuEu, or UU (u for *usual*). The gene E^a is referred to as the *atypical* gene; the sera of people homozygous for this gene ($E^a E^a$ = AA) are only weakly active toward most substrates for cholinesterase and demonstrate increased resistance to inhibition of enzyme activity by dibucaine. The E^f gene (f for *fluoride resistant*) also gives rise to a weakly active enzyme but with increased resistance to fluoride inhibition. The E^s gene (s for *silent*) is associated with absence of enzyme or the presence of a protein with minimal or no catalytic activity. The mutations that give rise to the atypical and fluoride-resistant CHE variants involve a change in the structure of the active center. The variant enzymes (allelozymes) are less effective catalysts than the usual form; the affinity of the enzymes for the substrates is reduced (i.e., K_m is increased), and affinity for competitive inhibitors, such as dibucaine or fluoride, is similarly decreased. This gives rise to the characteristic dibucaine- or fluoride-resistant properties of the genetic variants that are exploited in their characterization.

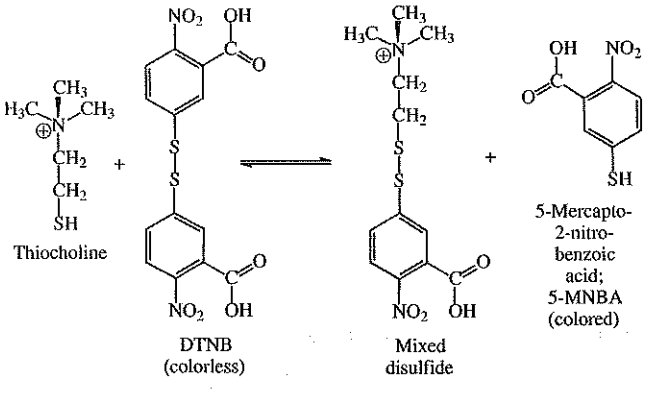
The homozygous forms, AA or FF, are found in 0.3% to 0.5% of the Caucasian population; their incidence among blacks is even lower. Inheritance of increased CHE activity has also been reported in a few families. This is apparently due to increased production of the usual allelozyme.

Clinical Significance[109]

Measurements of CHE activity in serum are used (1) as a test of liver function, (2) as an indicator of possible insecticide poisoning, and (3) for the detection of patients with atypical forms of the enzyme who are at risk of prolonged responses to certain muscle relaxants used in surgical procedures.



Measurement of serum CHE activity can serve as a sensitive indicator of the synthetic capacity of the liver. In the absence of genetic causes or known inhibitors, any decrease in CHE activity reflects impaired synthesis of the enzyme by the liver. A 30% to 50% CHE decrease is observed in acute hepatitis and in chronic hepatitis of long duration. Decreases of 50% to 70% occur in advanced cirrhosis and carcinoma with metastases to the liver. CHE is essentially normal in obstructive jaundice except when the cause is malignant. Serial measurement of CHE has been promoted as an indication of prognosis in patients with liver disease and for monitoring liver function after liver transplantation.



Among the organic phosphorus compounds that inhibit cholinesterase activity are many insecticides, such as parathion, sarin, and tetraethyl pyrophosphate. Workers in agriculture and in organic chemical industries may be subject to poisoning by inhalation of these materials or by contact with them. Obviously, if enough material is absorbed to inactivate all the acetylcholinesterase of nervous tissue, death will result. Both cholinesterases are inhibited, but the activity of the serum enzyme falls more rapidly than does that of the erythrocyte enzyme. A 40% drop in CHE activity occurs before the first symptoms are felt, and a drop of 80% is required before neuromuscular effects become apparent. Near-zero concentrations of enzyme activity require emergency treatment with such enzyme reactivators as pyridine-2-aldoxime. Upon retesting, in 3 to 5 days the CHE activity should increase by 15% to 20% if a significant organophosphate-induced inhibition has previously occurred.

Succinyldicholine (suxamethonium) and mivacurium, drugs used in surgery as muscle relaxants, are hydrolyzed by CHE, and their pharmacological effect normally persists only long enough to meet the needs of the surgical procedure. In patients with low enzyme activities or in those with a weakly active variant, destruction of the drug will not occur rapidly enough, and the patient may enter a period of prolonged paralysis of the respiratory muscles (apnea) requiring mechanical ventilation until the drug effects gradually wear off. Preoperative screening has been advocated to identify patients in whom suxamethonium administration may lead to complications. The degree of drug sensitivity varies with the phenotype of the patient. Total CHE activity is highest in individuals who are homozygous for the usual allele and progressively lower in those who are heterozygous for the usual and a variant allele, those who are homozygous or heterozygous for variant alleles, and those in whom two "silent" alleles are paired and no activity is detected. Subjects who possess one normal allele (i.e., who are heterozygous for the normal and a variant allele) usually produce enough enzyme to protect them against suxamethonium sensitivity, whereas patients with paired variant alleles (either as homozygotes or heterozygotes) show various degrees of sensitivity. The phenotypes most susceptible to apnea after succinylcholine administration are AA, AS, FF, FS, SS, AF, and to some extent UA. Measurements of total CHE activity and determination of the "dibucaine number" and "fluoride number" are needed to characterize CHE variants fully. The latter values indicate the percentage inhibition of enzyme activity toward specified substrates in the presence of standard concentrations of dibucaine or fluoride.

Methods for the Determination of Serum Cholinesterase Activity

Many of the contemporary methods use acylthiocholine esters as substrates. These substrates are hydrolyzed at approximately the same rate as choline esters, and the thiocholine formed can be measured by reaction with chromogenic disulfide agents, such as 5,5′-dithio-bis (2-nitrobenzoate) (DTNB) (Ellman's reagent). The reaction of the thiocholine product with colorless DTNB forms colored 5-MNBA, which is measured spectrophotometrically at 410 nm. The iodide salts of acetylthiocholine, propionylthiocholine, butyrylthiocholine, and succinylthiocholine all have been used as substrates. The reactions for butyrylthiocholine, with DTNB as the chromogen, are:

The clinical question being asked may influence the choice of substrate suitable for measuring the enzyme. Measuring CHE activity using succinyldithiocholine is the method of choice to diagnose succinylcholine sensitivity, purely based on the enzyme activity recorded in serum. This method is, however, well suited for other clinical applications of the test.[116]

Kalow and Genest, using benzoylcholine as a classic substrate, demonstrated the qualitative difference in CHEs. Based on the differences as sensitivity to inhibition by the local anesthetic dibucaine, they developed a simple test to classify the type of CHE as usual, intermediate, or atypical. With 10^{-5} mol/L dibucaine ("dibucaine number"), the usual CHE is inhibited by 80%, but atypical CHE is inhibited by only 20%. Subjects heterozygous for the normal and atypical gene show about 60% inhibition of CHE. To differentiate other genotypes, sodium fluoride can be used as CHE inhibitor.

Serum is the sample of choice. Enzyme activity in serum is stable for several weeks if the specimen is stored under refrigeration, and for several years if stored at –20 °C. Moderate hemolysis does not interfere if separated serum has been centrifuged to remove red blood cell ghosts.

Reference Intervals

Using the succinyldithiocholine/DTNB method at 37 °C, the reference interval for healthy adults with the usual CHE genotype was estimated to be 33 to 76 U/L for women and 40 to 78 U/L for men, respectively. The median activity in individuals with heterozygous genotype was 22 U/L (range 5 to 35 U/L), and for atypical homozygotes 1.5 U/L (range 1 to 4 U/L).[142] A value <23 U/L was approximately five times as likely to occur in a succinyldicholine-sensitive individual as in a normal one.[116] At birth, CHE activity is lower than adult values by about 50%. It increases during the next 3 to 6 years to exceed adult values by about 30%. From the fifth year of life, the activity starts to decrease before stabilizing at the adult value, which is reached at puberty. There is a significant CHE decrease (30%) during pregnancy and early puerperium, explained by hemodilution.

CHE phenotyping, based on the determination of dibucaine (DN) and fluoride (FN) numbers, has been established:

Phenotype	DN Range	FN Range
UU	≥77	≥55
UF	72-76	≥53
UA	48-72	≥44
AF	45-59	<44
FF	64-69	<44
AA	<35	*

*Redundant for AA phenotype attribution.

PANCREATIC ENZYMES

Assays of serum AMY, lipase (LPS), trypsin (TRY), chymotrypsin (CHY), and elastase 1 (E1) are applied to investigation of pancreatic disease. Pancreatic function and pathology are discussed in Chapter 48.

AMYLASE

α-Amylase (EC 3.2.1.1; 1,4-α-D glucan glucanohydrolase; AMY) is an enzyme of the hydrolase class that catalyzes the hydrolysis of 1,4-α-glucosidic linkages in polysaccharides. Both straight-chain (linear) polyglucans, such as amylose, and branched polyglucans, such as amylopectin and glycogen, are hydrolyzed, but at different rates. In the case of amylose, the enzyme splits the chains at alternate α-1,4-hemiacetal (—C—O—C—) links, forming maltose and some residual glucose; maltose, glucose, and a residue of limit dextrins are formed if branched-chain polyglucans are used as substrate. The enzyme does not attack the α-1,6-linkages at the branch points. AMYs are calcium metalloenzymes, with the calcium absolutely required for functional integrity. However, full activity is displayed only in the presence of various anions—such as chloride, bromide, nitrate, cholate, or monohydrogen phosphate—with chloride and bromide being the most effective activators. AMY in human serum has a moderately sharp pH optimum at 6.9 to 7.0.

AMYs normally occurring in human plasma are small molecules with molecular weights varying from 54,000 to 62,000. The enzyme is thus small enough to pass through the glomeruli of the kidneys, and AMY is the only plasma enzyme normally found in urine. AMY is present in a number of organs and tissues.[215] The greatest concentration is present in the salivary glands, which secrete a potent AMY (S-type) to initiate hydrolysis of starches while the food is still in the mouth and esophagus. The action of the S-AMY, once referred to as *ptyalin,* is terminated by acid in the stomach. In the pancreas, the enzyme (P-type) is synthesized by the acinar cells and then secreted into the intestinal tract by way of the pancreatic duct system. In the intestinal tract, effective action of pancreatic and intestinal AMY is favored by the mildly alkaline conditions in the duodenum. Intestinal maltase then further hydrolyzes maltose to glucose. AMY activity is also found in extracts from semen, testes, ovaries, fallopian tubes, striated muscle, lungs, and adipose tissue. The enzyme is also found in colostrum, tears, and milk. Some tumors of lung and ovary may also contain considerable AMY activity. The enzyme found in urine is derived from the plasma. Ascitic and pleural fluids may contain AMY as a result of the presence of a tumor or pancreatitis.

The enzyme present in normal serum and urine is predominantly of pancreatic (P-AMY) and salivary gland (S-AMY) origin. These isoenzymes are products of two closely linked loci on chromosome 1. AMY isoenzymes also undergo posttranslational modification of deamidation,

glycosylation, and deglycosylation to form a number of isoforms. Indeed, nonenzymic deamidation appears to be the mechanism for "aging" that occurs when AMY is sequestered (e.g., pancreatic pseudocysts) or subjected to prolonged in vitro storage. Although P-AMY is not glycosylated, S-AMY may exist in both glycosylated and deglycosylated forms; these isoforms can be separated in both serum and urine using isoelectric focusing or electrophoresis.

Clinical Significance

Blood AMY activity is normally low and constant and greatly increases in acute pancreatitis and salivary gland inflammation. In acute pancreatitis, a rise in serum AMY activity occurs within 5 to 8 hours of symptom onset; activities return to normal by the third or fourth day. A fourfold to sixfold elevation in AMY activity above the upper reference limit is usual, with maximal concentrations attained in 12 to 72 hours. The magnitude of the elevation of serum enzyme activity is not related to the severity of pancreatic involvement; however, the greater the rise, the greater the probability of acute pancreatitis. A portion of the clearance of AMY from the circulation is via renal excretion into the urine, and increased serum activity is reflected in an increase of urinary AMY activity. As compared with serum AMY, urine AMY reaches higher concentrations and persists for longer periods. The clinical specificity of AMY for the diagnosis of acute pancreatitis is, however, low (20% to 60%, depending on the mix of the patient population studied) since increased values are also found in a number of acute intraabdominal disorders and in several extrapancreatic conditions (Table 21-4).

Biliary tract diseases, such as cholecystitis, cause up to fourfold elevations of the serum AMY activity as a result of either primary or secondary pancreatic involvement. Various intraabdominal events can lead to a significant increase in serum AMY activities up to a fourfold elevation and sometimes beyond. Such increases may be due to leakage of the P-AMY from the intestine into the peritoneal cavity and then into the circulation. Peritonitis and acute appendicitis have been reported to produce a slight elevation (up to twofold and threefold) of serum AMY activity. Serum AMY is normal in most patients with ectopic pregnancies, but increases have been seen in advanced cases of ruptured ectopic pregnancy.

In renal insufficiency the serum AMY activity is increased in proportion to the extent of renal impairment (usually, no more than five times the upper reference limit). Hyperamylasemia also occurs in neoplastic diseases. Tumors of the lung and serous and mixed (serous and mucinous) carcinomas of the ovary can produce hyperamylasemia (with an S-type isoenzyme mobility) with elevations as high as 50 times the upper reference limit. Salivary gland lesions caused by infection, irradiation, obstruction, surgery, and tumor have all been reported as producing a significant S-type hyperamylasemia. Postoperative hyperamylasemia occurs in about 20% of all patients subjected to a wide variety of surgical interventions, including extraabdominal procedures. Increases of about four times the upper reference limit are found in as many as 80% of patients with diabetic ketoacidosis. In acute alcoholic intoxication, about 10% of subjects have a threefold elevation. Finally, a wide variety of drugs must always be considered as possible causes of hyperamylasemia.

Macroamylases are sometimes present in sera and may cause hyperamylasemia; these are complexes between ordinary AMY (usually S-type) and IgG or IgA. These macroamylases cannot be filtered through the glomeruli of the kidneys because of their large size (greater than MW 200,000) and are thus retained in the plasma where their presence may increase AMY activity some twofold to eightfold above the upper reference limit. No clinical symptoms are associated with this disorder, but some of these cases have been detected during investigation of abdominal pain.

The lack of specificity of total AMY measurement has led to the interest in the direct measurement of P-AMY instead of total enzyme activity for the differential diagnosis of patients with acute abdominal pain. By applying the best decision limit (i.e., an activity equal to threefold the upper reference limit), the clinical specificity of P-AMY for the diagnosis of acute pancreatitis was greater than 90%.[144] The

TABLE 21-4 Causes of Hyperamylasemia

Pancreatic disease	Pancreatitis, any cause (P-AMY↑)*
	Pancreatic trauma (P-AMY↑)
Intraabdominal diseases other than pancreatitis	Biliary tract disease (P-AMY↑)
	Intestinal obstruction (P-AMY↑)
	Mesenteric infarction (P-AMY↑)
	Perforated peptic ulcer (P-AMY↑)
	Gastritis, duodenitis (P-AMY↑)
	Ruptured aortic aneurysm
	Acute appendicitis
	Peritonitis
	Trauma
Genitourinary disease	Ectopic, ruptured tubal pregnancy (S-AMY↑)
	Salpingitis (S-AMY↑)
	Ovarian malignancy (S-AMY↑)
	Renal insufficiency (Mixed)
Miscellaneous	Salivary gland lesions (S-AMY↑)
	Acute alcoholic abuse (S-AMY↑)
	Diabetic ketoacidosis (S-AMY↑)
	Macroamylasemia (Mixed)
	Septic shock (S-AMY↑)
	Cardiac surgery (S-AMY↑)
	Tumors (usually S-AMY↑)
	Drugs (usually S-AMY↑)

*Predominant isoenzyme type is shown in parentheses: *P-AMY,* pancreatic; *S-AMY,* salivary; *Mixed,* either or both isoenzymes may be present.

sensitivity in late detection of this condition is also notably improved with P-AMY. P-AMY values remain elevated in 80% of patients with uncomplicated pancreatitis 1 week after onset, when only 30% still show increased total AMY activity.[147] This long-standing increase in P-AMY activity in serum also makes redundant the traditional measurement of total AMY in urine, a test performed to achieve a better diagnostic sensitivity in the late phase of pancreatitis.

A decreased P-AMY activity in serum (less than the lower reference limit) identifies with high specificity patients with exocrine pancreatic insufficiency and steatorrhea and can make intubation tests for pancreatic function unnecessary. If, however, P-AMY is normal, a reduced pancreatic function cannot be excluded.[115]

Methods for the Determination of α-Amylase Activity[47]

Historically, saccharogenic, amyloclastic, and chromolytic starch methods were the assays of choice for determining AMY activity. These assays are now completely displaced in favor of ones with well-defined substrates with shorter glucosyl chains. The use of defined AMY substrates and auxiliary and indicator enzymes in the AMY assay has improved the reaction stoichiometry and has led to more controlled and consistent hydrolysis conditions. Substrates used include small oligosaccharides and 4-nitrophenyl (4-NP)-glycoside substrates.

When hydrolyzed by AMY, small oligosaccharides substrates have been found to give better-defined products than do starches. For example, both maltopentaose and maltotetraose show good stability, consistent hydrolysis products, and unambiguous reaction stoichiometry. Several variations of the reaction rate formulation have been devised. For example, the detection of glucose can be achieved by the hexokinase (EC 2.7.1.1) reaction:

$$\text{Maltopentaose} \xrightarrow{\textit{α-amylase}} \text{maltotriose} + \text{maltose}$$

$$\text{Maltotriose} + \text{maltose} \xrightarrow{\textit{α-glucosidase}} 5\ \text{glucose}$$

$$\text{Glucose} + \text{ATP} \xrightarrow{\textit{Hexokinase}} \text{G-6-P} + \text{ADP}$$

$$\text{G-6-P} + \text{NAD}^{\oplus} \xrightarrow{\textit{G-6-P dehydrogenase}} \text{6-P-gluconolactone} + \text{NADH} + \text{H}^{\oplus}$$

Maltose generation is detected by the maltose phosphorylase (EC 2.4.1.8) reaction, which avoids interference by the endogenous glucose of the sample.

Maltotetraose has also been used as a substrate in the following reaction scheme:

$$\text{Maltotetraose} \xrightarrow{\textit{α-amylase}} 2\ \text{maltose}$$

$$\text{Maltose} + \text{P}_i \xrightarrow{\textit{Maltose phosphorylase}} \text{glucose} + \text{glucose-1-P}$$

$$\text{Glucose-1-P} \xrightarrow{\textit{β-Phosphoglucomutase}} \text{Glucose-6-P}$$

$$\text{G-6-P} + \text{NAD}^{\oplus} \xrightarrow{\textit{G-6-P dehydrogenase}} \text{6-P-gluconolactone} + \text{NADH} + \text{H}^{\oplus}$$

With this method, for each bond hydrolyzed by AMY, two molecules of NADH are produced. This holds true only if neither glucose nor maltotriose is produced by the action of AMY. Later work has shown that these products are present in the reaction mixture in significant quantities. Thus the assay underestimates AMY activity.

4-NP-glycoside substrates are prepared by bonding 4-NP to the reducing end of a defined oligosaccharide. If the oligosaccharide is maltoheptaose (G7), the substrate is then 4-NP-G7. AMY splits this substrate to produce free oligosaccharides (G5, G4, and G3) and 4-NP-G2 (9%), 4-NP-G3 (31%), and 4-NP-G4 (60%). P-AMY hydrolyzes the substrate at a greater rate than does S-AMY in the ratio 1.8 : 1:

$$\text{4-NP-(glucose)}_7 \xrightarrow{\textit{α-amylase}} \text{4-NP-(glucose)}_{4,3,2} + \text{(glucose)}_{5,4,3}$$

$$\text{4-NP-(glucose)}_{4,3,2} \xrightarrow{\textit{α-glucosidase}} \text{4-NP-(glucose)}_4 + \text{x-glucose} + \text{NP}$$

G6, G1, 4-NP-G6, and 4-NP-G5 are not produced in appreciable quantities. In the original assay, the result of the combined hydrolysis by AMY in the specimen and by the reagent α-glucosidase (EC 3.2.1.20; maltase) is that more than 30% of the product is free NP. The free NP is detected by its absorbance at 405 nm. α-Glucosidase does not react with any oligosaccharide containing more than four glucose molecules in the chain; G4 is hydrolyzed only very slowly.[160] Problems arose with the use of the 4-NP-glycoside assay with regard to the poor stability of the reconstituted assay mixture because of the slow hydrolysis of the 4-NP-glycoside by α-glucosidase. This effect has been reduced by covalently linking a "blocking" group, e.g., a 4,6-ethylidene group (ethylidene-protected substrate [EPS]), to the nonreducing end of the molecule. The blocked substrate also shows a different and more advantageous hydrolysis pattern. Thus the ethylidene-4-NP-G7 substrate fragments approximately as 4-NP-G2 (40%), 4-NP-G3 (40%), and 4-NP-G4 (20%). Therefore liberation of 4-NP is increased; however, the reaction rate is reduced in proportion, so these two effects compensate for each other.[90] A novel-type α-glucosidase is available (recombinant enzyme AGH-211 from Toyobo Co., Japan) that completely hydrolyzes nitrophenylated substrates. As a result, the cleavage of one α-glucosidic

linkage by AMY results in the release of one molecule of 4-NP. IFCC has optimized this method at 37 °C, deciding to recommend it as a reference measurement procedure for AMY.[98]

An alternative method based on the 2-chloro-*p*-nitrophenol (CNP) indicator uses 2-chloro-*p*-nitrophenyl-α-D-maltotrioside (CNP-G3) as a substrate:

$$10\,\text{CNP} - \text{G3} \xrightarrow{\alpha\text{-amylase}} 9\,\text{CNP} + 1\,\text{CNP} - \text{G2} + 9\,\text{maltotriose} + 1\,\text{glucose}$$

This assay does not require glucosidases and is considered a "direct" assay. Its disadvantages have been stated to include its low substrate conversion rate compared with G4, G5, and G7 assays; the variation in molar absorptivity of CNP associated with changes in pH, temperature, and protein content; and the presence of the activator, potassium thiocyanate, causing allosteric changes to AMY and precluding the use of antibodies for P-AMY determination.[193]

With the exception of heparin, all common anticoagulants inhibit AMY activity because they chelate Ca^{2+}; citrate, EDTA, and oxalate inhibit it by as much as 15%. Therefore, AMY assays should be performed only on serum or heparinized plasma. AMY is quite stable; activity is fully retained during storage for 4 days at room temperature, 2 weeks at +4 °C, 1 year at −25 °C, and 5 years at −75 °C.

Reference Interval

Reference intervals for AMY are method dependent. Using the IFCC recommended method at 37 °C, the serum reference interval was 28 to 100 U/L.[77]

Analytical Methods and Reference Intervals for Amylase Isoenzymes

Methods for AMY isoenzymes based on electrophoresis, ion-exchange chromatography, isoelectric focusing, selective inhibition of the S-AMY by a wheat germ inhibitor, immunoprecipitation by a monoclonal antibody, and immunoinhibition have been introduced. However, only the methods based on the selective isoenzyme inhibition by monoclonal antibodies have shown sufficient precision, reliability, practicability, and analytical speed to allow the introduction of the P-AMY determination in clinical practice.

A double monoclonal antibody assay is commercially available that uses the synergistic action of two immunoinhibitory monoclonal antibodies to S-AMY. After the S-AMY activity is inhibited by the addition of the antibodies, the uninhibited P-AMY activity is measured using EPS-4-NP-G7 as a substrate.[159] The test has been the object of a number of evaluations that have described its characteristics, such as practicability even in emergency conditions, possibility of full automation, and high specificity for P-AMY.[194] False-positive P-AMY results have been reported in subjects with macroamylasemia, in whom the immunoglobulin complexed to AMY forms diminishes or voids the ability of monoclonal antibodies included in the test to efficiently inhibit S-AMY.

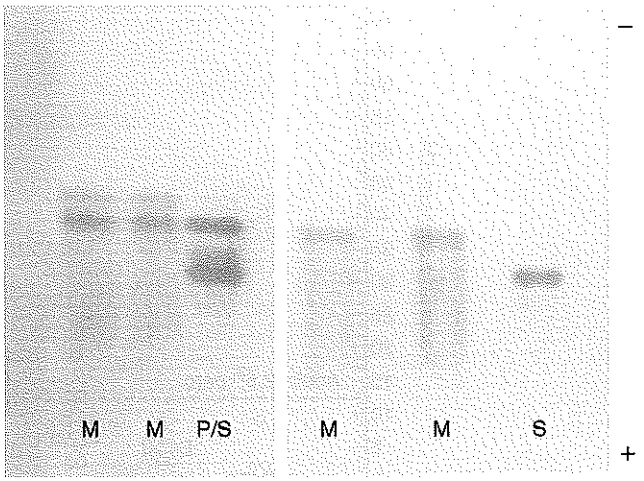


Figure 21-6 Cellulose acetate electrophoresis of amylase isoenzymes. *M*, Macroamylasemia; *P/S*, mixture of two samples containing, respectively, pancreatic juice and saliva; *S*, saliva. The anodal direction is downward.

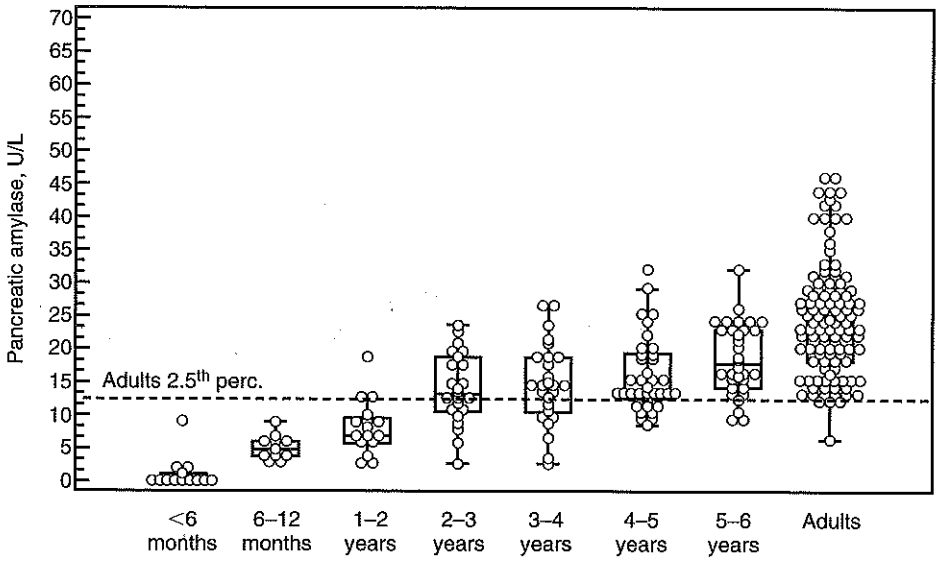
Upon electrophoresis, macro-AMY usually forms a broad migrating band, clearly different from the homogeneous bands that are produced by AMY isoenzymes present in serum (Figure 21-6). If electrophoretic separation is not available, precipitation of the macrocomplex by a polyethylene glycol (PEG) 6000 solution (240 g/L) represents a good alternative. Residual AMY activity of less than 30% in the supernatant is indicative of macroamylasemia.[201]

In normal adults, P-AMY represents approximately 40% to 50% of the total enzymatic activity in serum. Using the immunoinhibition method at 37 °C, the reference interval for P-AMY activity in sera from adults was 13 to 53 U/L.[77] After birth, serum S-AMY activity increases steadily with age and reaches normal adult values at 2 years of age. Serum P-AMY activity is not demonstrable in most children younger than 6 months, but activity rises slowly thereafter to reach adult levels at 5 years of age, reflecting the postnatal development of exocrine pancreatic function (Figure 21-7).

Lipase

Human lipase (EC 3.1.1.3; triacylglycerol acylhydrolase; LPS) is a single-chain glycoprotein with a molecular weight of 48,000 and an isoelectric point of about 5.8. The LPS gene resides on chromosome 10. LPS concentration in the pancreas is about 5000-fold greater than in other tissues, and the concentration gradient between pancreas and serum is ~20,000-fold.[137] For full catalytic activity and greatest specificity, the presence of bile salts and a cofactor called colipase, which is secreted by the pancreas, is required. Human LPS can also be fully activated in vitro by colipases from other species (e.g., porcine colipase); this property is used in analytical formulations of the LPS assay.[196]

Lipases are defined as enzymes that hydrolyze glycerol esters of long-chain fatty acids. Only the ester bonds at carbons 1 and 3 (α-positions) are attacked, and the products



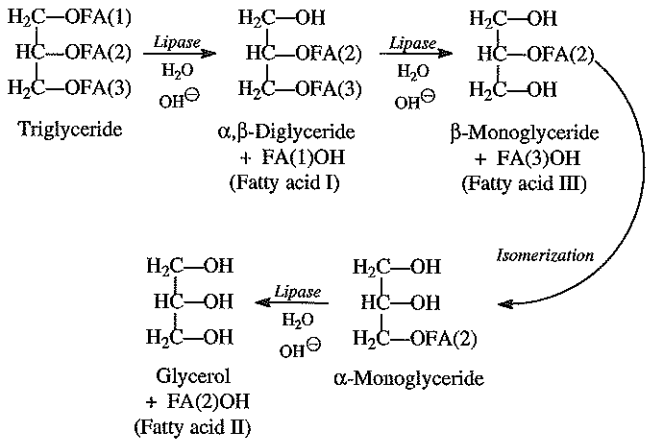


Figure 21-7 Activity values of pancreatic amylase in sera of healthy neonates and children compared with distribution in healthy adults.

of the reaction are 2 mol of fatty acids and 1 mol of 2-acylglycerol (β-monoglyceride) per mole of substrate. The latter is resistant to hydrolysis, probably because of steric hindrance, but it can spontaneously isomerize to the α-form (3-acylglycerol). This isomerization permits the third fatty acid to be split off but at a much slower rate. A scheme for the steps in the complete hydrolysis of a molecule of triglyceride to glycerol and three fatty acids is:

LPS acts only when the substrate is present in an emulsified form at the interface between water and the substrate. The rate of LPS action depends on the surface area of the dispersed substrate. Bile acids ensure that the surface of the dispersed substrate remains free of other proteins, including lipolytic enzymes, by lining the surface of the insoluble substrate and the aqueous medium. LPS seems to gain access to the substrate surface in the following manner: Colipase attaches to a micelle of bile salts, thus forming a colipase–bile salt complex that reconfigures the structure of colipase with the exposure of a site with high affinity and high specificity for LPS, which therefore attracts LPS and anchors it to the substrate surface, allowing enzyme action to proceed.[140]

Most of the LPS activity found in serum derives from the pancreas, but some is also secreted by the lingual salivary glands and gastric, pulmonary, and intestinal mucosa. LPS is a small enough molecule to be filtered through the glomerulus. It is totally reabsorbed by the renal tubules, and it is not normally detected in urine. Evidence suggests that pancreatic LPS may exist in at least two isoforms, although the exact nature of these is unknown.[137] The complete absence of LPS has been reported. Such congenital absence results in fat malabsorption and severe steatorrhea.

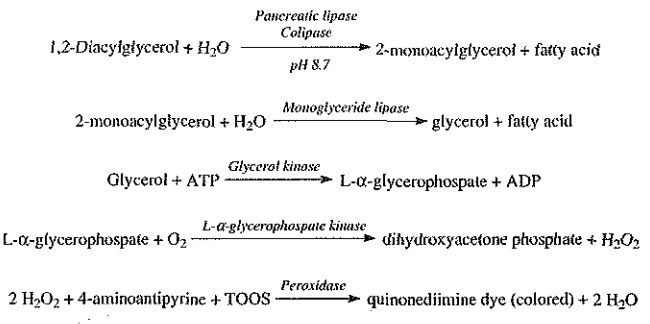
Clinical Significance

LPS measurement on serum is used to diagnose acute pancreatitis. The clinical sensitivity is 80% to 100% depending upon the selected diagnostic cutoff. The clinical specificity is 80% to 100% depending upon the mix of patient population studied. After an attack of acute pancreatitis, serum LPS activity increases within 4 to 8 hours, peaks at about 24 hours, and decreases within 8 to 14 days. Concentrations often remain elevated longer than those of AMY do. Elevations between 2 and 50 times the upper reference limit have been reported. The increase in serum LPS activity is not necessarily proportional to the severity of the attack.[196]

Acute pancreatitis is sometimes difficult to diagnose because it must be differentiated from other acute intraabdominal disorders with similar clinical findings, such as perforated gastric or duodenal ulcer, intestinal obstruction, or mesenteric vascular obstruction. In differential diagnosis, elevation of serum LPS activity greater than 5 times the upper reference limit is a more specific diagnostic finding than increases in serum AMY activity.[146]

Obstruction of the pancreatic duct by a calculus or by carcinoma of the pancreas may increase serum LPS activity, depending on the location of the obstruction and the amount of remaining functioning tissue. In patients with a reduced glomerular filtration rate, the serum LPS activity is increased. Thus care should be exercised in the interpretation of elevated serum LPS values in the presence of renal disease. Finally, investigation of the biliary tract by endoscopic retrograde pancreatography or treatment with opiates (which causes the sphincter of Oddi to contract) may increase serum LPS activity.

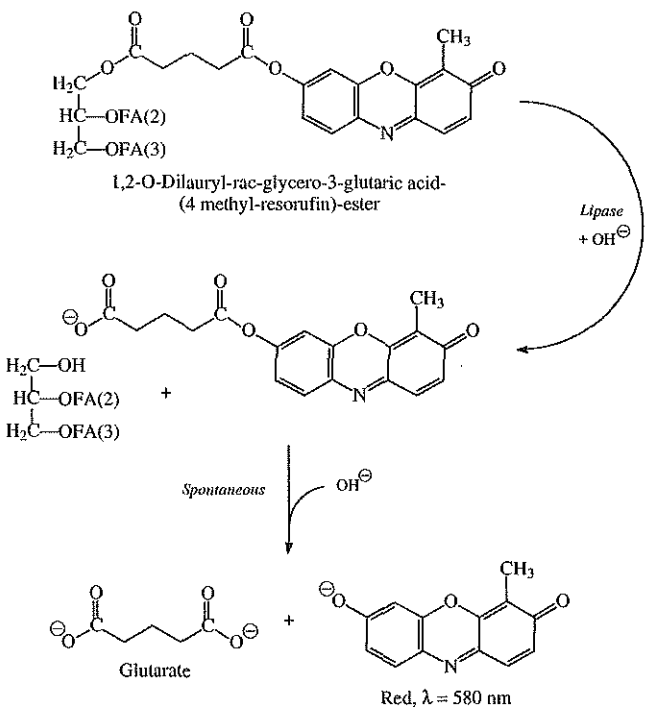
Methods for Measuring Lipase Activity



Many LPS methods have been described; they have used both triglyceride and nontriglyceride substrates and titrimetric, turbidimetric, spectrophotometric, fluorometric, and immunological techniques. In general, long-chain triglyceride (and some diglyceride) substrates have demonstrated a correlation of results with the clinical state that is superior to that with methods using other substrates.[95]

In titrimetric methods, LPS catalyzes the hydrolysis of fatty acids from an emulsion of olive oil or oleic acid. The fatty acids liberated are titrated with dilute alkali. Kinetic versions use an automated potentiometric titrator (an instrument commonly referred to as a "pH-stat"). The amount of alkali used is recorded as a function of time and serves as a measure of fatty acid produced during the reaction. This method has been proposed as reference measurement procedure, useful in the evaluation of new LPS methods.[6]

In the turbidimetric method, LPS catalyzes the hydrolysis of fatty acids from an emulsion of oleic acid with a simultaneous decrease in the turbidity of the reaction mixture. Absorbance at 340 nm is read and the ΔA/min is taken as a measure of LPS activity. This method requires the use of a LPS calibrator. Turbidities have occasionally been observed to increase rather than to decrease during the reaction period. Such increases have frequently been observed in specimens containing rheumatoid factor. The method linearity (~3 times the upper reference limit) is limited, with many clinical samples needing to be diluted. The upper reference limit at 30 °C was reported to be 150 U/L.



A number of substrates and complex auxiliary and indicator systems are used in spectrophotometric methods. In the Ortho Diagnostics Vitros spectrophotometric reaction rate LPS slide method, the (synthetic) substrate is 1-oleoyl-2,3-diacetylglycerol and the emulsifier dodecylbenzene sulfonate. LPS activity is measured by a complex auxiliary and indicator enzyme system to produce a colored dye detectable at 540 nm. However, the substrate is likely to be more specific for intestinal than pancreatic LPS and may be subject to interference by postheparin lipase and pancreatic carboxylesterase.[191] An upper reference limit of 200 U/L at 30 °C has been reported.

In the enzymatic reaction rate diglyceride assay for LPS, the following sequence of indicator and auxiliary enzymes is used:

TOOS is sodium *N*-ethyl-*N*-(2-hydroxyl-3-sulfopropyl)-m-toluidine, and its oxidation produces an intensely colored dye detectable at 550 nm. The suggested upper reference limit is 45 U/L at 37 °C.

A new synthetic substrate (1,2-O-dilauryl-rac-glycero-3-glutaric acid-(4-methyl-resorufin)-ester), consisting of two glycerol ether and one ester bonds, has been proposed. LPS hydrolyze the latter bond in an alkaline medium to an unstable dicarbonic acid ester that spontaneously hydrolyzes to yield glutaric acid and methylresorufin; this is a bluish-purple chromophore with peak absorption at 580 nm.

The rate of methylresorufin formation is directly proportional to the LPS activity of the sample. The upper reference limit is 38 UL at 37 °C.

LPS activity in serum is stable at room temperature for 1 week; sera may be stored for 3 weeks in the refrigerator and for several years if frozen.

TRYPSIN

Trypsin (EC 3.4.21.4; no systematic name; TRY) is a serine proteinase characterized by the presence at the active site of serine and histidine, both of which participate in the catalytic process. TRY hydrolyzes the peptide bonds formed by the carboxyl groups of lysine or arginine with other amino acids, although esters and amides involving these amino acids are actually split more rapidly than peptide bonds.

The acinar cells of the human pancreas synthesize two different trypsins (1 and 2) in the form of the inactive proenzymes (or zymogens), trypsinogens-1 and -2. These zymogens are stored in zymogen granules and are secreted into the duodenum under the stimulus of either the vagus nerve or the intestinal hormone cholecystokinin-pancreozymin. The two trypsinogens represent approximately 19% of the total protein in pancreatic juice; trypsinogen-1 is present at about fourfold the concentration of trypsinogen-2. In the intestinal tract, the trypsinogens are converted to the active enzyme TRY by the intestinal enzyme enterokinase or by preformed TRY (autocatalysis).[92]

TRY-1 is also described as cationic and TRY-2 as anionic because of their differing electrophoretic mobility; the cationic form predominates and is the better-documented enzyme. TRY-1 and TRY-2 have molecular weights of 25,800 and 22,900 and pI values of 4.6 to 6.5 and greater than 6.5, respectively. TRY-2 differs from TRY-1 in that it rapidly undergoes autolysis at neutral or alkaline pH values and Ca^{2+} does not stabilize it against autolysis. Because the two trypsins show little immunological cross-reactivity, specific immunoassay of each of them is possible.

When trypsinogens are converted to active TRY, a small peptide is cleaved from the *N*-terminal region of trypsinogen (trypsinogen activation peptide or TAP). Determinations of urinary TAP seem to provide useful information on the severity of acute pancreatitis.[48]

Materials such as soybeans, lima beans, and egg whites contain natural TRY inhibitors—small polypeptides such as α_1-antitrypsin (α-1-protease inhibitor) and α_2-macroglobulin—that combine irreversibly with TRY and inactivate it by blocking the active center. Similar nondialyzable TRY inhibitors are present in pancreatic juice, serum, and urine. These inhibitors protect plasma and other proteins against hydrolysis by TRY and other proteases if for some reason any appreciable quantity of the enzyme enters the vascular system. The absence of α_1-antitrypsin is associated with an increased tendency toward panlobular emphysema in early life; this example illustrates the effects of uninhibited proteases on organ function.

Clinical Significance

Trypsin-1 (Cationic Trypsin)[114]

In healthy individuals, free trypsinogen-1 is the major form found in serum. After an attack of acute pancreatitis, serum TRY-1 rises in parallel with serum AMY activity to peak values ranging from 2 to 400 times the upper reference limit. The distribution of the different forms of TRY-1 appears to be related to the type and severity of the acute pancreatitis. Thus in the mildest form of acute pancreatitis, 80% to 99% of the TRY-1 exists as free trypsinogen-1, with smaller proportions existing as bound TRY-1. In the more severe forms, in which mortality ranges from 20% to more than 50%, the proportion of free trypsinogen-1 may be as low as 30% of the total, with appreciable proportions existing as the α_1-antitrypsin- and α_2-macroglobulin-bound TRY-1.[30]

TRY-1 in serum is elevated in chronic renal failure, as is serum AMY. Thus renal failure must be ruled out when interpreting elevated concentrations. In chronic pancreatitis without steatorrhea, plasma concentrations of TRY-1 do not differ from those found in health; when steatorrhea is present, however, fasting concentrations are extremely low.[54] In the relapsing phase of chronic pancreatitis, plasma TRY may be considerably elevated. In carcinoma of the pancreas, TRY concentrations may be high, normal, or even low.

In comparison with P-AMY and LPS measurements, TRY-1 is a more difficult test to perform, requiring several hours to complete. As there is no distinct role of TRY estimation in the routine management of patients with acute pancreatitis, this test is considered of limited clinical value.

In cystic fibrosis, plasma TRY concentrations have been reported to be high in neonates; as the disease progresses, the concentration falls. Dried blood specimens have been suggested for use in screening tests.[60,158]

Trypsin-2 (Anionic Trypsin)

Serum trypsinogen-2 increases more than trypsinogen-1 in acute pancreatitis.[73] Consequently, large amounts of trypsinogen-2 are excreted into urine. Using both quantitative immunofluorimetric assay and qualitative rapid test strips to measure urinary trypsinogen-2, Stenman's group at the University of Helsinki showed high sensitivity and negative predictive value for diagnosis of acute pancreatitis on admission to the hospital. However, the positive predictive value of this test is low.[86]

As noted above, newly formed TRY is inactivated by complexing with α_1-antitrypsin, and assays of this serum complex with TRY-2 have preliminarily shown that this determination can be superior to that of either trypsinogen-2 or AMY in acute pancreatitis.[64] To date, no confirmation of these findings has been published.

Methods for the Determination of Trypsin

Early studies used catalytic assays, but it was soon recognized that other proteolytic enzymes present in serum could also hydrolyze the same substrates. A major advance has been the development of immunoassays to quantify TRY in blood. In the case of TRY-1, immunoassays detect trypsinogen-1, TRY-1, and TRY-1-α_1-antitrypsin complex. They do not detect the TRY-1-α_2-macroglobulin complex, for which different assays are necessary. Free TRY-1 is not usually found in serum; it is always complexed.

Commercial immunoassays are available for measurement of TRY-1. As there is no assay standardization, reference limits are method-dependent.

A rapid (5 minute) urinary trypsinogen-2 test strip is available, which is based on the use of immunochromatography with monoclonal antibodies. At urinary trypsinogen-2 concentrations greater than 50 μg/L, a blue line develops on the strip, and the test is considered positive.

CHYMOTRYPSIN

Chymotrypsin (EC 3.4.21.1; no systematic name; CHY) is also a serine proteinase. It hydrolyzes peptide bonds involving carboxyl groups of Trp, Leu, Tyr, or Phe, with preference for the aromatic residues. The specificity of CHY thus contrasts with that of pepsin, which splits bonds involving amino groups of the aromatic amino acids. CHY also demonstrates hydrolytic activity for other types of bonds in the following order: esters (especially *N*-substituted tyrosine esters) > amide > peptides.[5]

The acinar cells of the human pancreas synthesize two different chymotrypsins (1 and 2, the latter being the major species) in the form of the inactive proenzymes (or zymogens), chymotrypsinogens-1 and -2. These zymogens are stored in granules and are secreted like trypsinogen into the pancreatic duct. In the intestinal tract, the chymotrypsinogens are converted to CHY by the action of TRY. CHY is more resistant than TRY to degradation in the intestine; it is therefore the enzyme of choice for assay in feces.

CHY-1 is also described as anionic and CHY-2 as cationic because of their differing electrophoretic mobility; the cationic form predominates. The molecular weight of both forms is approximately 25,000. There is close immunological similarity between the chymotrypsins and chymotrypsinogens. CHY, like TRY, is bound in plasma by α_1-antitrypsin and α_2-macroglobulin.

Clinical Significance[54]

The major application of the assays that measure CHY activity in stool is in the investigation of chronic pancreatic insufficiency. CHY in feces is often reduced below the lower reference limit in such subjects in whom steatorrhea has developed, but it is not useful in identifying subjects with early pancreatic insufficiency. (See Table 48-15.) CHY measurement in patients with chronic pancreatic insufficiency treated with oral pancreatic enzyme supplements may indicate whether the therapy is adequate or whether increased supplementation is necessary.

Methods for the Determination of Chymotrypsin in Feces

Synthetic substrates are commonly used for this application. A sensitive kinetic assay has been developed that uses succ-ala-ala-pro-phe-4-nitroanilide as a substrate, and made commercially available. Prior treatment of the stool specimen with detergent to release particle-bound CHY is necessary. A cheap device enables a small stool sample to be homogenized, extracted, and centrifuged with minimal inconvenience. The extract is mixed with the substrate, which is hydrolyzed by CHY to produce free 4-nitroanilide, measured photometrically at 405 nm.

CHY activity in stool remains constant at room temperature for up to 7 days.

Reference Interval

The lower reference limit of fecal CHY activity, measured at 37 °C, was found to be 12 U/g stool.[110]

ELASTASE-1

Human elastase-1 (EC 3.4.21.36; no systematic name; E1) is an anionic protease belonging to the family of serine proteases. It is a carboxyendopeptidase that catalyzes hydrolysis of native elastin, the major structural fibrous protein in connective tissue, with a special affinity for the carboxyl group of alanine, valine, and leucine.

Human E1 is synthesized by the acinar cells of the pancreas along with the other digestion enzymes, and is composed of 240 amino acids, with a MW of about 26,000. The enzyme is synthesized as a preproelastase. After processing to proelastase, it is stored in the zymogen granules and later it is activated to elastase by TRY in the duodenum, undergoing minimal degradation during intestinal transit.

Historically, any proteinases that hydrolyze elastin have been named elastases. The genes coding for the elastases are clustered on chromosome 19, and three main types of enzymes are known: (1) pancreatic E1, (2) pancreatic elastase-2 (EC 3.4.21.71), and (3) pancreatic endopeptidase-3 (EC 3.4.21.70), also called cholesterol-binding proteinase.[44]

Clinical Significance[54]

E1 measurement in stool is the most reliable and sensitive noninvasive procedure for the diagnosis of chronic pancreatic insufficiency. However, such a test does not consistently separate mild to moderate insufficiency cases from healthy controls (see Table 48-15). Unlike fecal CHY, E1 provides no information helpful to the therapeutic management of the patient.

Methods for the Determination of Elastase-1 in Feces

An ELISA method in a microplate sandwich format is commercially available to measure E1 mass concentrations in stool samples.

The enzyme has been found to be stable in stool samples for up to 1 week at room temperature.

Reference Interval

The lower reference limit of fecal E1 concentration was found to be 200 μg/g stool.

BONE ENZYMES

Bone enzymes are direct products of active osteoblasts (bone ALP) and osteoclasts (tartrate-resistant acid phosphatase).

Alkaline Phosphatase (Bone Isoform)

Bone, liver, and kidney isoforms of ALP are posttranslational modifications of the same gene product and are identified by their unique carbohydrate content (see Fig. 21-4). They have been described above in the section on liver enzymes. Bone ALP is produced by the osteoblast and has been demonstrated in matrix vesicles deposited as "buds" derived from the cell's membrane. The enzyme is therefore an excellent indicator of global bone formation activity.

Clinical Significance in Bone Disease

Among the bone diseases, the highest concentrations of bone ALP are encountered in Paget's disease (osteitis deformans) as a result of the action of the osteoblastic cells as they try to rebuild bone that is being resorbed by the uncontrolled activity of osteoclasts. Values from 10 to 25 times the upper reference limit are not unusual, and in broad terms the increase reflects the extent of disease. In vitamin D deficiency (osteomalacia and rickets), concentrations two to four times normal may be observed, and these fall slowly to normal on treatment. Primary hyperparathyroidism and secondary hyperparathyroidism are associated with slight to moderate elevations of bone ALP in serum, the existence and degree of elevation reflecting the presence and extent of skeletal involvement. Very high enzyme concentrations are present in patients with osteogenic bone cancer. Concentrations can be slightly increased in osteoporosis, but osteoporotic individuals are not clearly distinguished from age-matched controls. Transient elevations may be found during healing of bone fractures. Physiological bone growth increases bone ALP in serum, and this accounts for the fact that in the sera of growing children, enzyme concentration is 1.5 to 7 times that in healthy adult serum, the maximum being earlier in girls than in boys.

Methods for the Determination of Bone Alkaline Phosphatase

In general, separation of tissue-nonspecific ALP forms (i.e., bone and liver) is difficult because of structural similarity. Bone ALP in serum can be measured by heat inactivation (a poor method), lectin precipitation, and immunochemical and electrophoretic methods (see the section on liver enzymes).

Immunoassays for bone ALP, which measure either enzyme activity or mass, are commercially available; cross-reactivity with liver isoform however, has been established:

Assay	Type	Percentage of Cross-Reactivity
Beckman Tandem-R-Ostase	Mass-based IRMA	12.7-16.5
Beckman Tandem-MP-Ostase	Mass-based ELISA	8.1-16.2
Metra Alkphase-B	Activity-based EIA	5.9-20.0

This general limitation should be borne in mind when interpreting test results.

With the use of immunoassays measuring bone ALP concentrations, the enzyme is said to be stable at –20 °C for 2 years.

Reference Intervals

Using the electrophoretic procedure, the reference interval for bone ALP activity in healthy adults is 10 to 50 U/L.[148] Mean (SD) bone ALP concentrations, determined by immunoassays in healthy adults, were 13 µg/L.[32]

Acid Phosphatase (Tartrate-Resistant)

Under the name of acid phosphatase (EC 3.1.3.2; orthophosphoric-monoester phosphohydrolase [acid optimum]; ACP) are included all phosphatases with optimal activity below a pH of 7.0.

ACP is present in lysosomes, which are organelles present in all cells with the possible exception of erythrocytes. Extra lysosomal ACPs are also present in many cells. The greatest concentrations of ACP activity occur in prostate, bone (osteoclasts), spleen, platelets, and erythrocytes. The lysosomal and prostatic enzymes are strongly inhibited by dextrorotatory tartrate ions, whereas the erythrocyte and bone isoenzymes are not. The majority of the normally low ACP activity of (unhemolyzed) serum is of a tartrate-resistant type (TR-ACP) and probably originates mainly in osteoclasts. Activities of this fraction are increased physiologically in growing children and pathologically in conditions of increased osteolysis and bone remodeling.[119]

At least four ACP-determining genes have been identified and mapped. The erythrocyte ACP gene is located on chromosome 2 and is polymorphic, and a further gene on chromosome 19 encodes the TR-ACP expressed in osteoclasts and other tissue macrophages, such as alveolar macrophages and Kupffer cells (type 5 ACP). Type 5b has been proposed as a specific and sensitive marker of osteoclastic activity. The genes encoding the tartrate-inhibited lysosomal and prostatic ACPs, mapped to chromosomes 11 and 13 respectively, exhibit considerable homology.[123]

The ACPs are unstable, especially at temperatures above 37 °C and at pH above 7.0. Some of the enzyme forms in serum are particularly labile, and more than 30% of the ACP activity may be lost in 3 hours at room temperature. Acidification of the serum specimen to a pH below 6.5 aids in stabilizing the enzyme activity.

Clinical Significance

Slight or moderate elevations in serum TR-ACP activity often occur in Paget's disease, in hyperparathyroidism with skeletal involvement, and in the presence of malignant invasion of the bones by cancers, such as breast cancer in women. Increased concentrations of the osteoclast-derived ACP are also present in serum in osteoclastoma (giant-cell tumor), an osteoclastic neoplasm, and in osteopetrosis (marble bone disease) in which the osteoclasts fail to resorb bone. High concentrations

of TR-ACP in serum of these patients reflect increased osteoclastic activity, whether appropriate as in normal bone growth, or damaging as in osteopetrosis. This isoenzyme is therefore a potentially useful marker of conditions with a marked osteolytic component. However, TR-ACP appears to show relatively small dynamic changes in comparison with other markers of bone resorption, e.g., those related to type I collagen metabolism. This may be attributable to the fact that the enzyme is released into the sealed osteoclast microenvironment, rather than directly into circulation.

The only nonbone condition in which elevated activities of TR-ACP are found in serum is Gaucher's disease of spleen, a lysosomal storage disorder. Its source in this disease is the abnormal macrophages in spleen and other tissues, which overexpress this normal macrophage constituent. The hairy cells of hairy-cell leukemia (leukemic reticuloendotheliosis) also express the osteoclast-type ACP, providing a useful histological marker. However, in this condition, the isoenzyme does not enter the plasma in increased amounts.

Although once widely used to detect or monitor carcinoma of the prostate, determination of ACP (tartrate-inhibited) activity in serum is now rarely used for this purpose. It has been replaced by prostate-specific antigen (PSA).

Methods for the Determination of Tartrate-Resistant Acid Phosphatase

Continuous-monitoring methods for assay of TR-ACP activity are based on the principle introduced by Hillmann in which α-naphthol released from its phosphate ester forms a colored product with the stabilized diazonium salt of 2-amino-5-chlorotoluene-1,5-naphthalene disulfonate (Fast Red TR).[9] The introduction of alcohols, such as 1,5-pentanediol, accelerates the reaction and increases sensitivity by acting as phosphate acceptors in transfer reactions. The addition of sodium tartrate inhibits the sensitive isoenzymes (i.e., prostatic and lysosomal ACPs) if they are present in the sample.

Immunological methods based on antibodies raised against TR-ACP have been described. A recently introduced method uses a monoclonal antibody to bind serum TR-ACP in a solid-phase format. After the capture, osteoclastic enzyme is specifically determined by measuring its activity at pH 6.1.

Serum should be immediately separated from erythrocytes and stabilized by the addition of 50 µL of acetic acid (5 mol/L) per milliliter of serum to lower the pH to 5.4, at which the enzyme is stable. Under these conditions, TR-ACP activity is maintained at room temperature for several hours, for up to a week if the serum is refrigerated, and for 4 months if stored at −20 °C. Hemolyzed serum specimens are contaminated with considerable amounts of the erythrocyte tartrate-resistant isoenzyme and should be rejected.

Reference Intervals

In the sera of healthy adults, the reference interval for TR-ACP activity, measured at 37 °C, is 1.5 to 4.5 U/L. Children show higher TR-ACP activities (3.4 to 9.0 U/L).

RED CELL ENZYMES

Erythrocytes perform a variety of functions, the most important being the binding, transport, and delivery of oxygen to all tissues. To do so, they must be capable of passage through microcapillaries, which is achieved by modifications of the erythrocyte's biconcave shape. This is possible because, unlike most other cells in the body, human erythrocytes lose the nucleus and organelles before entering the circulation from the marrow. In addition, remaining RNA in the reticulocyte is lost within the first 2 days in circulation, thereby making further protein synthesis no longer possible.

Normal human red cells survive in the circulation for approximately 120 days, using energy to maintain the electrolyte gradient between plasma and red cell cytoplasm and to keep hemoglobin and the sulfhydryl groups of the red cell enzymes and membrane proteins in the reduced state. Because of the absence of a nucleus and mitochondria, the red cell is incapable of generating energy via the (oxidative) Krebs cycle and depends mainly on the anaerobic conversion of glucose by the Embden-Meyerhof pathway (EMP or direct glycolytic pathway) and the oxidative hexose monophosphate pathway (HMP or pentose phosphate shunt) (Figure 21-8). Numerous red cell enzymes are involved in these pathways, thereby providing the cell with the necessary moles of ATP.

Deficiencies of any of these red cell enzymes may result in impaired ATP generation and consequently loss of function of the erythrocyte. By far the majority of these disorders are hereditary in nature, although acquired deficiencies have been described, mainly in malignant disorders involving the bone marrow. Hereditary enzymatic defects in these pathways disturb the erythrocyte's integrity, shorten its cellular survival, and produce chronic nonspherocytic hemolytic anemia (CNSHA). Deficiencies of some enzymes, however, do not lead to chronic hemolytic anemia, but to acute episodes of severe hemolysis when there is increased oxidative stress on the red cell (as in some types of glucose-6-phosphate dehydrogenase deficiency).

A number of these enzymes are expressed in other tissues as well but cause a notable deficiency predominantly in red blood cells because of the life span of the erythrocyte after the loss of protein synthesis. Once an enzyme is degraded or otherwise becomes nonfunctional, it cannot be replaced by new or other "compensating" proteins because of the lack of nucleus, mitochondria, ribosomes, and other cell organelles in mature red cells. Disorders have been described in the EMP, HMP, Rapoport-Luebering cycle, the glutathione pathway (Figure 21-9), purine-pyrimidine metabolism and methemoglobin reduction.

This section describes the red cell enzymes involved in the metabolic pathways of clinical importance in the human red cell and the disorders associated with defects in these pathways. In addition, diagnostic strategies and pitfalls of laboratory diagnostics for these enzyme deficiencies will be explained. The laboratory methods described have been

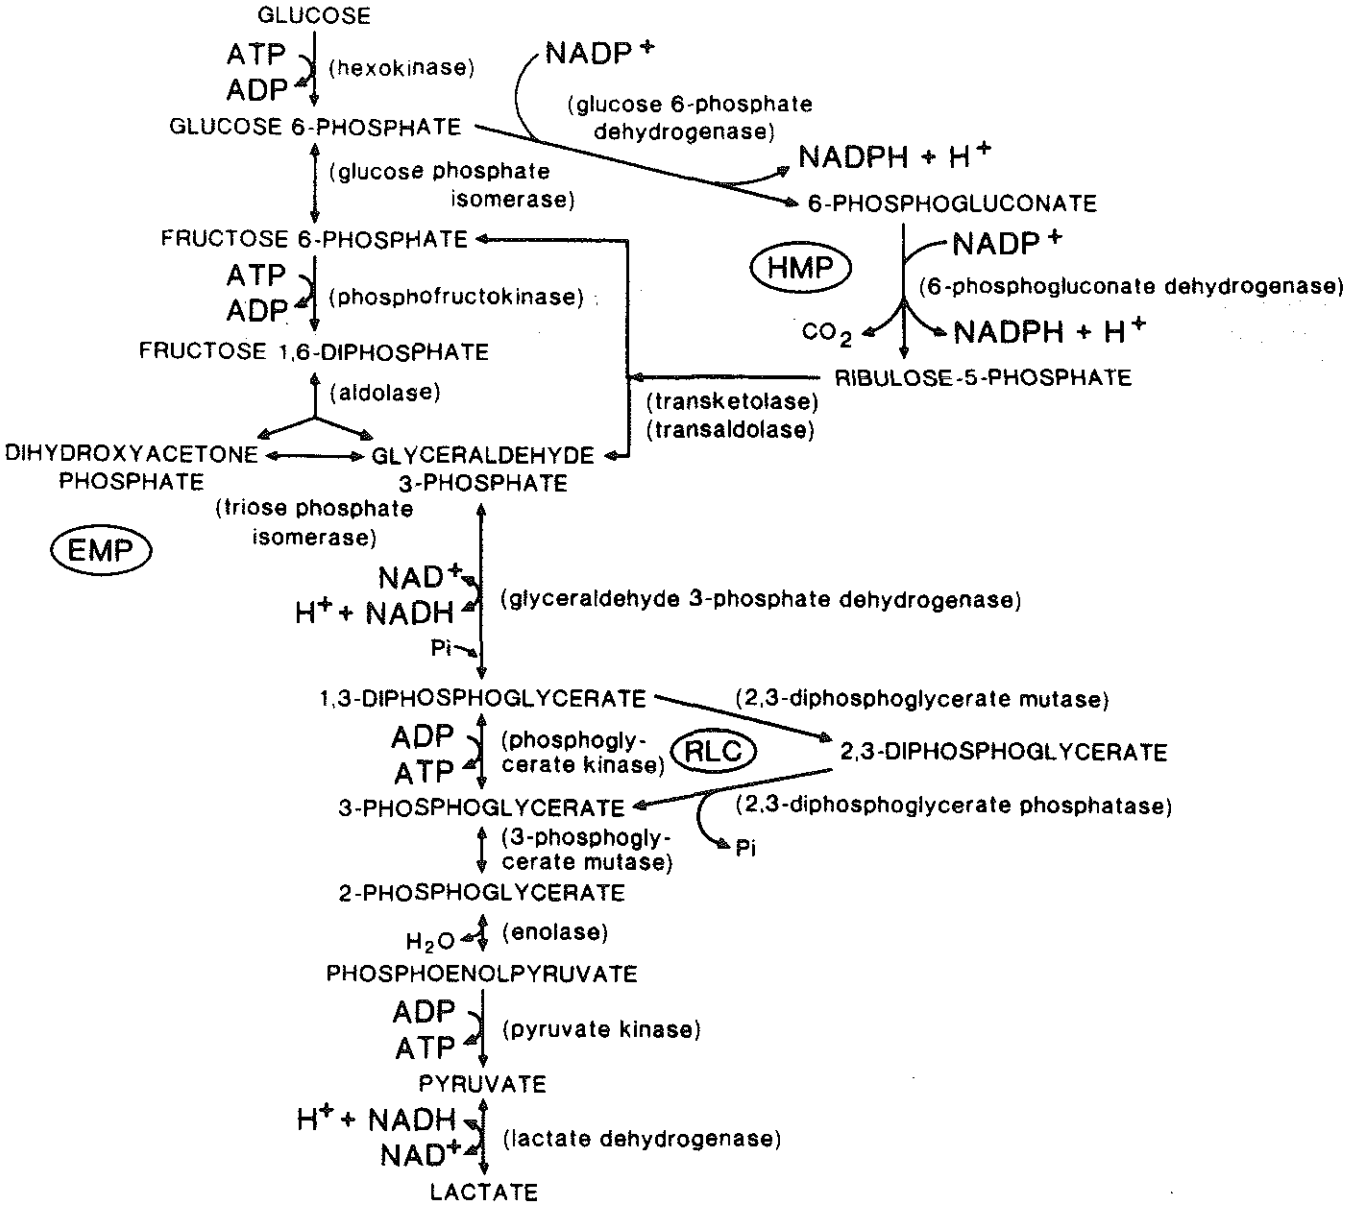


Figure 21-8 Major glycolytic pathways of the erythrocyte. Substrates are in uppercase type, and enzymes are in parentheses. *EMP,* The Embden-Meyerhof pathway; *HMP,* hexose monophosphate pathway or pentose shunt; *RLC,* the Rapoport-Luebering cycle; *ADP,* adenosine diphosphate; *ATP,* adenosine triphosphate; *NAD+,* nicotinamide-adenine dinucleotide; *NADH,* reduced nicotinamide-adenine dinucleotide; *NADP+,* nicotinamide-adenine dinucleotide phosphate; *NADPH,* reduced nicotinamide-adenine dinucleotide phosphate. The step from ribulose-5-phosphate, which is shown as being catalyzed by transketolase and transaldolase, is an abbreviation of this portion of the HMP.

used now for decades and are well documented. During the last few years, however, molecular diagnostics has proven to be an indispensable tool in diagnosing hereditary red cell enzyme deficiencies.

The Embden-Meyerhof Pathway

Glucose is the energy source of the red cell. In the normal situation (without increased "oxidative stress"), 90% of glucose is catabolized anaerobically to pyruvate or lactate by the direct glycolytic pathway or EMP. Although one mole of ATP is used by hexokinase and an additional mole of ATP by phosphofructokinase, the net gain is 2 moles of ATP per mole of glucose, since a total of 4 moles of ATP are formed per mole of glucose by phosphoglycerate kinase and pyruvate kinase. In addition, reducing energy is generated in the form of reduced nicotinamide-adenine dinucleotide (NADH) in the step catalyzed by glyceraldehyde phosphate dehydrogenase. This reducing energy can be used to reduce

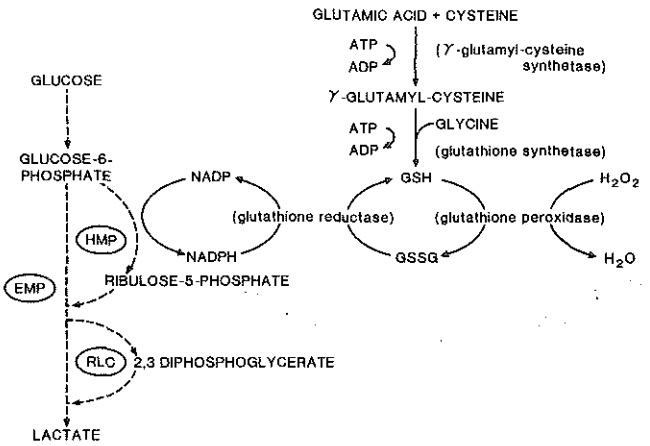

Figure 21-9 Interrelationship of hexose monophosphate and glutathione pathways. *GSH,* Reduced glutathione; *GSSG,* oxidized glutathione.

methemoglobin to hemoglobin by NADH-cytochrome b5 reductase. If this reaction takes place, the end product of the glycolysis is pyruvate. However, if NADH is not reoxidized here, it is used in reducing pyruvate to lactate by lactate dehydrogenase in the last step of the glycolysis.

Although the pathway is reasonably straightforward, it is subjected to a complex mechanism of inhibiting and stimulating factors. Some of the enzymes involved are allosterically stimulated by products of the pathway (such as pyruvate kinase [PK] by fructose diphosphate), while others may serve as strong inhibitors (such as glucose 6-phosphate for hexokinase [HK]).

Hexokinase

Hexokinase (HK; EC 2.7.1.1) catalyzes the phosphorylation of glucose to glucose-6-phosphate (G6P) using ATP as a phosphoryl donor. The activity of HK is significantly higher in reticulocytes compared with mature red cells, where it is very low. The HK reaction is one of two rate-limiting steps in this pathway, the other being the phosphofructokinase reaction.

In mammalian tissues, four isozymes of HK with different enzymatic properties exist, HK-I to III with an M_r of 100,000 kDa and HK-IV (or glucokinase) with an M_r of 50,000 kDa. HK-I to III are considered to have evolved from an ancestral 50 kDa HK by gene duplication and fusion. Consequently, both the *C*- and *N*-terminal halves of HK-I to HK-III show extensive internal sequence similarity, but only in the case of HK-II was catalytic function maintained in both the *C*- and *N*-terminal halves. HK-I and HK-III have further evolved into enzymes with respectively catalytic (*C*-terminal) and regulatory (*N*-terminal) halves.

HK-I is the predominant HK isozyme in tissues that depend strongly on glucose use for their physiological functioning, such as brain, muscle, and erythrocytes. HK-I displays unique regulatory properties in its sensitivity to inhibition by physiological concentrations of the product G6P and, moreover, relief of this inhibition by inorganic phosphate and by high concentrations of glucose.[217] In addition, the enzyme depends on magnesium. HK is a homodimer[3,124] and the recent determination of structures of human and rat HK-I has provided substantial insight into ligand-binding sites and subsequent modes of interaction.[1-3,124,181]

Erythrocytes contain a specific subtype of HK (HK-R),[125] which is encoded by the HK-I gene (*HK1*), localized on chromosome 10q22 and spanning more than 100 kb.[4] The structure of *HK1* is complex: it encompasses 25 exons that, by tissue-specific transcription, generate multiple transcripts by alternative splicing of different 5′ exons.[4] Erythroid-specific transcriptional control results in a unique red blood cell (RBC)–specific mRNA that differs from HK-I mRNA at the 5′ untranslated region (5′-UTR) and at the first 63 nucleotides of the coding region.[126,127,171] Consequently, HK-R lacks the porin-binding domain that mediates HK-I binding to mitochondria.[128]

HK deficiency (OMIM 235700)* is a rare, recessively inherited disease with chronic nonspherocytic hemolytic anemia as the predominant clinical feature. The phenotypic expression of the disease is heterogeneous, as with most glycolytic red cell enzyme deficiencies. The spectrum ranges between severe neonatal hemolysis and death to a fully compensated chronic hemolytic anemia. Patients benefit in general from a splenectomy. Red cell morphology is normal. Since HK activity is dependent on red cell age, reticulocytosis, always present in HK-deficient patients, may obscure enzyme deficiency. Other age-dependent red cell enzymes (e.g., pyruvate kinase and/or G6PD) should be measured simultaneously as an internal control to assess the influence of reticulocyte enzyme activity.

Seventeen families with HK deficiency have been described to date[81] and only three patients have been characterized at the DNA level.[26,27,83,203] One is presumably a splice site mutation, resulting in the skipping of exon 6. In the same patient, a leucine residue at position 529 was mutated into a serine, affecting enzyme stability possibly because of interference with G6P binding.[26,27] The second patient characterized had a homozygous missense mutation in exon 15, leading to substitution of a highly conserved threonine by serine at residue 680 in the enzyme's active site where it interacted with phosphate moieties of ADP, ATP, and inhibitor G6P.[203] The last mutation was lethal and identified in a fetus. A deletion of 9.5 kb of the HK gene, leading

*OMIM stands for Online Mendelian Inheritance in Man. It is a World Wide Web database (http://www.ncbi.nlm.nih.gov/omim) developed under the auspices of the National Center for Biotechnology Information (NCBI). It consists of a catalog of human genes and genetic disorders and contains textual information, pictures, and reference information. It also contains links to NCBI's Entre/database of MEDLINE articles and sequence information. Individual disorders may be found by entering the OMIM numbers into the search engine of the database.

to deletion of exons 5 to 8 of the HK gene was detected, resulting in a null allele.[83]

Glucose Phosphate Isomerase

G6P isomerase (GPI; EC 5.3.1.9) (also known as phosphoglucose isomerase [PGI]), catalyzes the interconversion of G6P and fructose 6-phosphate (F6P), the second step of the EMP. As a result of this reversible reaction, products of the hexose monophosphate pathway can be recycled to G6P. Besides being a housekeeping enzyme of glycolysis, GPI exerts outside the cell cytokine properties and is involved in several extracellular processes.[76] In addition, autoantibodies against GPI seem to be involved in rheumatoid arthritis.[172] GPI is a crucial enzyme, since GPI knockout mice die in the embryological state.[211,212]

Recently, the crystal structure of human GPI was resolved. The enzyme is a multifunctional protein composed of homodimers, each with a molecular mass of 63 kDa. A dimer of GPI is a prerequisite for catalytic activity, because the active site of the enzyme is composed of polypeptide chains from both subunits.[39,162]

The gene encoding GPI is located on chromosome 19q13.1[108] and consists of 18 exons, spanning at least 50 kb, with a cDNA 1.9 kb in length.[218]

GPI deficiency (OMIM 172400) is an autosomal recessive disease and is, after G6PD and PK deficiencies, the third most common red cell enzymopathy. Homozygous or compound heterozygous patients have mild to severe chronic hemolytic anemia, with an enzyme activity less than 25% of normal. Neonatal death, hydrops fetalis, and in some patients neurological symptoms have been reported. Few patients have been described with hemolytic crises after oxidative stress.[70,105,161,213] Usually there is a marked reticulocytosis. Unlike for HK, the GPI activity in reticulocytes is only marginally higher than that of older cells. Heterozygous patients are hematologically normal, with an enzyme activity of 40% to 60%. Red cell morphology is in general without any abnormalities. Patients benefit from a splenectomy. A striking feature of nearly all GPI mutants is that they are thermolabile, while kinetic properties are more or less unaffected. The normal enzyme is very stable.

Around 50 families with GPI deficiency have been described worldwide.[91] In total, 29 mutations are characterized at the molecular level, of which 24 were missense mutations, 3 nonsense, and 2 splice site mutations.[91] Mapping of these mutations in the crystal structure of human GPI gives insight into the molecular mechanisms causing hemolytic anemia in this disorder.[162] Mutations could be placed in three groups: the first affecting the precise structure of the enzyme, the second those that disrupt the dimer interface, and the third those mutants that directly affect the active site.[162]

Phosphofructokinase

Phosphofructokinase (PFK; EC 2.7.1.11) catalyzes the phosphorylation of fructose-6-phosphate by ATP to fructose-1,6-diphosphate. This conversion is rate limiting. The enzyme is a homotetramer or heterotetramer with a molecular mass of around 380 kDa. Three distinct subunits have been identified in humans: PFK-M (muscle), PFK-L (liver), and PFK-P (platelet).[207] In erythrocytes, five isoenzymes can be identified with varying subunit composition (M_4, M_3L_1, M_2L_2, ML_3, and L_4).

The genes for the PFK-M, PFK-L, and PFK-P subunits have been cloned.[46,96,128]

Phosphofructokinase deficiency (OMIM 171850) is a rare autosomal recessively inherited disorder. Since red cells contain both M and L subunits, mutations affecting the genes coding for these subunits will affect enzyme activity. Thus when the PFK deficiency mutation affects only the L subunit, RBCs have only M_4 and are PFK deficient. In such cases, there is a mild hemolytic disorder without myopathy. However, when the M subunit is deficient, muscle PFK is virtually absent together with partial PFK deficiency in RBCs, which will have only L_4. Therefore deficiency of the M subunit causes myopathy and a mild hemolytic disorder.

To date, 15 alleles associated with PFK deficiency have been identified. Missense, nonsense, and a frameshift mutation along with mutations affecting splicing have been characterized in the PFK-M gene.[50]

Patients usually have only a mild, well-compensated hemolytic anemia with an enzyme activity of approximately half normal. The enzyme is relatively unstable in vitro and assays should be carried out, preferably, on fresh blood samples.

Aldolase

Aldolase (fructose-1,6-biphosphate aldolase; EC 4.1.2.13) catalyzes the reversible conversion of fructose-1,6-biphosphate to glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. The enzyme is a tetramer of identical subunits of 40 kDa. Three isoenzymes are identified to date: aldolases A, B, and C. Aldolase A is the isoenzyme that is expressed in the RBC, but also in muscle and brain.

The gene for aldolase A spans 7530 bases and consists of 12 exons. Several transcription-initiation sites were identified along with tissue-specific splicing.[74]

Only three cases of aldolase deficiency have been described.[25,87,89] Beutler et al[25] have described a boy with an unstable enzyme with mental retardation and hemolytic anemia and dysmorphic features. Kishi et al[87] described a patient with severe hemolytic anemia, exacerbated by infection, but none of the features described by Beutler et al. Kishi identified the mutation, leading to a conversion of aspartic acid at position 128 to glycine. Kreuder et al[89] reported on a boy with hemolytic anemia and myopathy caused by aldolase A deficiency. They identified a mutation, causative of an amino acid substitution at position 206 (Glu to Lys).

Aldolase activity is notably influenced by red cell age, thus the activity of this enzyme is increased in patients with hemolytic disease.

Triosephosphate Isomerase

Triosephosphate isomerase (TPI; EC 5.3.1.1) is the enzyme (26.75 kDa) of the anaerobic glycolytic pathway with the

highest activity. It catalyzes the interconversion of glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. TPI is a dimer with two identical subunits of 248 amino acids with an eight-stranded barrel structure.[101] There are no isoenzymes known, only three distinct electrophoretic forms due to minor posttranslational modifications.[152,219] In RBCs, TPI is not maturation dependent.

TPI deficiency (OMIM 190450) is a relatively rare autosomal recessive disorder, characterized by hemolytic anemia at onset and severe neuromuscular defects usually at 6 months to 2 years of age. Heterozygotes are clinically normal, but have half normal red cell TPI activity. In the erythrocyte there is a twentyfold to sixtyfold increase in the concentration of dihydroxyacetone phosphate.[169] TPI is transcribed from a single gene, located on chromosome 12p13; the gene spans 3.5 kb and contains seven exons.[31] To date, 14 mutations in the gene encoding TPI have been identified.[165] The most common mutation produces an amino acid substitution at position 104 (glutamate acid to aspartic acid). The other mutations are found only in individual families.

Phosphoglycerate Kinase

Phosphoglycerate kinase (PGK, EC 2.7.2.3) catalyzes the reversible conversion of 1,3-diphosphoglycerate to 3-phosphoglycerate, generating one molecule of ATP.

The reaction catalyzed by PGK can be bypassed by the Rapoport-Luebering shunt (see Figure 21-8), thereby losing the gain of one ATP molecule.

Two isoenzymes PGK-1 and PGK-2 exist, with PGK-1 being ubiquitously expressed in all somatic cells. *PGK-2* is an autosomal gene expressed only in spermatozoa.[106] PGK-1 is a monomeric enzyme of 417 amino acids.[67] The three-dimensional structure of horse muscle PGK (highly homologous with the human enzyme) displays two lobes connected by a hinge, allowing conformational freedom to occur.[16]

The gene encoding PGK-1 is located on the long arm of the X-chromosome (Xq13), making PGK deficiency an X-linked disorder. The gene spans 23 kb and is composed of 11 exons.[36,43,111] Fourteen different mutations in the PGK-1 gene have been described, leading to PGK deficiency (OMIM 311800, for an overview see reference 49). The disease is characterized by hemolytic anemia of varying severity, neurological abnormalities, and muscle disease. However, patients have been described with hemolysis, but without the neurological or muscle symptoms. Thus the expression of the disease can be highly variable.[49] The genotype-phenotype relations of the disorder are still poorly understood.

Pyruvate Kinase

Pyruvate kinase (PK; EC 2.7.1.40) catalyzes the conversion of phosphoenolpyruvate to pyruvate with the concomitant generation of the second molecule of ATP in glycolysis. The activity of PK depends on red cell age. The younger the red cells, the higher the activity.

The enzyme is dependent on K^{2+} and Mg^{2+} or Mg^{2+}.[58] The product of the reaction, pyruvate, is crucial for several metabolic pathways. Because of this important end product, PK is thought to be—together with PFK—the major regulatory enzyme of glycolysis.

PK is active as a homotetramer or heterotetramer, composed of one of four different tissue-specific subunits. The M1 subunit is found in skeletal muscle, heart, and brain. The M2 type is dominant in all tissues in early fetal life, but also in adult tissues including leukocytes and platelets. The L subunit is predominant in the liver, while only the R subunit is found in the erythrocyte. During erythropoiesis, PK-M2 (a homotetramer of M2 subunits) is expressed in normoblasts and reticulocytes. PK-R (a homotetramer of R subunits) increases progressively during erythrocyte maturation, replacing PK-M2. Proteolytic degradation of the 574 amino-acid-long R subunit converts it to the 543 amino-acid-long R′ subunit. This occurs in aging mature erythrocytes, resulting in the preponderance of a PK isoenzyme consisting of a heterotetramer of two R subunits and two R′ subunits in the mature aging red cell.[78-80] Why ultimately no homotetramer of four R′ subunits is formed is unknown.

The red cell enzyme is allosterically regulated by fructose-1,6-diphosphate (FDP). Sigmoid kinetics occur by increasing concentrations of the substrate phosphoenolpyruvate.

The crystal structure of human red cell PK has been elucidated.[67] The enzyme resembles closely the structures of cat and rabbit muscle type PK. The subunit is composed of an *N*-terminal domain, an A-domain containing the active site, a B-domain capable of rotating away from the A-domain generating either the "open" or "closed" conformation, and a C-domain with the binding site for FDP.

The gene encoding both the M1- and M2-type subunits is located on chromosome 15q24-q25, and the respective subunits are formed by alternative splicing.[130,190] The R and L subunits are transcribed from a single gene located on chromosome 1q21, by the use of tissue-specific promoters.[82] The gene consists of 12 exons over 9.5 kb. Exon 1 is specific for the R type, while exon 2 is solely expressed in the L type. Exons 3 to 12 are common to both subtypes.

Pyruvate kinase deficiency (OMIM 266200) is the most common cause of nonspherocytic hemolytic anemia due to defective glycolysis. The allelic frequency is estimated to be around 2%.[22] The consequent lack of sufficient energy, which is required for normal functioning and cellular survival, shortens the life span of the mature PK-deficient erythrocyte. Consequently, PK-deficient patients display a phenotype of nonspherocytic hemolytic anemia albeit with variable clinical severity.[104] The clinical symptoms vary from neonatal death to a well-compensated hemolytic anemia. Patients benefit in general from a splenectomy. Pyruvate kinase deficiency is transmitted as an autosomal recessive disease. To date, more than 130 mutations in *PKLR* have been reported to be associated with pyruvate kinase deficiency (see Figure 21-10; for overview see reference 221). Most (70%) of these mutations are missense mutations affecting conserved residues in structurally and functionally important domains of PK. Splice site mutations, a deletion,

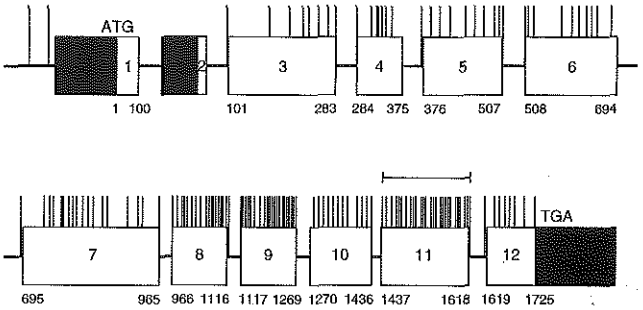

Figure 21-10 Schematic representation (not drawn to scale) of the *PKLR* gene and its erythroid-specific promoter. Exons are numbered and depicted as rectangles, separated by intervening sequences (introns), 5′ and 3′ noncoding sequences are colored black. Nucleotides are numbered according to the erythroid-specific cDNA, the initiator methionine and stop codon (TGA) are indicated. In the figure, the position of each of the more than 130 mutations that have, to date, been described in association with PK deficiency[221] (and our own unpublished observations) is indicated. The horizontal line that encompasses exon 11 indicates the deletion of this exon, as identified on the cDNA level. The figure shows that mutations are encountered throughout the gene, although there tends to be a clustering of mutations toward the 3′-end, in particular in exons 8, 9, and 11.

and point mutations in the red cell–specific promoter have been described. One promoter mutation is of particular interest, as it silences the red cell–specific PK gene completely. This mutation is located in a putative binding domain for an as-yet unidentified trans-acting factor that mediates the effects of factors necessary for regulation of PK gene expression during red cell differentiation and maturation.[204] Because PK activity is related to the age of the red cell, other glycolytic enzymes should be measured simultaneously to assess the influence of reticulocytosis on the enzyme activity.

Modeling the known mutations in the three-dimensional computer model of the tetramer and expressing mutant enzymes in in vitro model systems helps to better understand the genotype-phenotype interactions, since these are still poorly understood in this disorder.[200,202,210]

Lactate Dehydrogenase

Lactate dehydrogenase (LD) catalyzes the conversion of pyruvate to lactate, the last step in the EMP. Deficiency of this enzyme is not associated with hematological disease. LD is described elsewhere.

Hexose Monophosphate Pathway

Normally, approximately 10% of glucose is catabolized through the hexose monophosphate pathway, but this fraction may be markedly increased when there is oxidative stress, as is the case when there is an infection or use of certain drugs. The principal function of the hexose monophosphate pathway is to reduce 2 moles of NADP to NADPH by oxidizing G6P. NADPH is required for a variety of biosynthetic pathways, for the stability of catalase and the regeneration and preservation of the reduced form of glutathione. These processes are crucial in the cell to detoxify hydrogen peroxide and protect the cell from oxidative stress. Since the red cell has no other sources of NADPH, it heavily depends on the prime enzyme of this reaction, glucose 6-phosphate dehydrogenase (G6PD).

Glucose 6-Phosphate Dehydrogenase

Glucose 6-phosphate dehydrogenase (G6PD; EC 1.1.1.49) is expressed in all cells and catalyzes the first step in the hexose monophosphate pathway, the conversion of glucose 6-phosphate to 6-phosphogluconate. This step generates 1 mol of NADPH. The activity of G6PD is higher in reticulocytes than in mature red cells.

The enzyme is a dimer (predominantly) or tetramer (pH dependent) in the active form composed of identical subunits, 515 amino acids long and about 59 kDa.[208] The three-dimensional structure of human G6PD has been elucidated.[7] The monomer is built up by two domains, an N-terminal domain and a large $\beta + \alpha$ domain with an antiparallel nine-stranded sheet. The interface between the two monomers is of crucial importance for proper activity of the enzyme and is located in this second domain.

The gene coding for G6PD is located on the X-chromosome (Xq28), spans 18 kb, and consists of 13 exons. Exon 1 is noncoding. The promoter shares many features common to other housekeeping genes.[103]

G6PD deficiency (OMIM 305900) is the most common enzymopathy, affecting 400 million people worldwide. The disease is X-linked. More than 400 different types of G6PD variants have been described, leading to different enzyme activities associated with a wide range of biochemical and clinical phenotypes. The variants are grouped into five categories according to the level of enzyme activity and clinical phenotype.

The clinical expression of the disease is heterogeneous and five different clinical syndromes can be recognized:

- Drug-induced hemolysis
- Infection-induced hemolysis
- Favism
- Neonatal jaundice (NNJ)
- Chronic nonspherocytic hemolytic anemia (CNSHA)

The majority of G6PD-deficient individuals develop hemolysis only when oxidative stress occurs, as with infections and after ingestion of certain drugs or fava beans. Outside these periods, they are usually asymptomatic. However, G6PD deficiency can also lead to mild to severe chronic hemolysis, exacerbated by oxidative stress. These variants are class I mutants (Table 21-5). Nearly half of the mutations encoding class I G6PD variants directly affect the subunit interface of the G6PD dimer[7] and are located in exons 10 and 11. However, it is not always clear what the exact phenotype of particular mutations will be, since some identical variants might still lead to different phenotypes.[75] The availability of

TABLE 21-5 Classes of Severity of Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency

Class I	Severe deficiency associated with chronic hemolytic anemia.
Class II	Severe deficiency (<10% residual activity), usually without hemolytic anemia.
Class III	Moderate to mild deficiency (10% to 60% residual activity) (e.g., G6PD A).
Class IV	Very mild or no deficiency (e.g., G6PD A).
Class V	Increased activity (only one such variant has been described, G6PD Hektoen).

the 3-D structure of the human enzyme makes a better understanding of the effect of mutations in G6Pd feasible.

The literature on G6PD and G6PD deficiency is extensive and has been reviewed.[20,99,208]

Transketolase

Transketolase is decreased in thiamin deficiency. Low values of it have also been found in chronic alcoholism.

Rapoport-Luebering Cycle

The Rapoport-Luebering cycle, which is unique to mammalian RBCs, provides the principal physiological means for regulation of the O_2 affinity of hemoglobin.[17,18,198] From the point of view of O_2 transport, one might assert that the Embden-Meyerhof pathway of the RBCs serves principally to generate 2,3-DPG, because quantitatively this substance is the principal glycolytic intermediate of RBCs; the concentration of 2,3-DPG is about equal to the sum of all other glycolytic intermediates. The 2,3-DPG content of RBCs is increased in all anemias; in all but one, the increase is inversely proportional to the hemoglobin concentration.[17] The single exception is PK deficiency, in which 2,3-DPG is increased disproportionately to the hemoglobin deficit as a result of the "bottleneck" at the PK step and of a retrograde accumulation of products of glycolysis. The increase in 2,3-DPG in anemias results in a decrease in O_2 affinity of hemoglobin so that O_2 is more readily transferred to tissues. The O_2 affinity of hemoglobin is also influenced by slight changes in pH of the blood; a corresponding sensitivity to pH exists in the Rapoport-Luebering cycle, which again permits change in 2,3-DPG concentration to fine tune the O_2 affinity of hemoglobin.

Two enzymes involved in the Rapoport-Luebering cycle are diphosphoglyceromutase (2,3-DPG mutase [DPGM]; EC 5.4.2.4) and diphosphoglycerate phosphatase (2,3-DPG phosphatase [DPGP]; EC 3.1.3.13). The same protein molecule is responsible for both DPGM and DPGP activities.[71,167] This multifunctional enzyme regulates the concentration of 2,3-DPG in the erythrocyte and thus is very important in regulating O_2 affinity of hemoglobin. DPGM is a homodimer, with subunits of 258 amino acids (30 kDa).

The single locus for the gene of DPGM is located on chromosome 7q22-34 and is fully expressed only in erythroid tissue during the late stages of differentiation.[209]

DPGM deficiency is a rare autosomal recessive disorder, resulting in reduced synthesis of 2,3-DPG. As a consequence, blood oxygen affinity is increased, accounting for the polycythemia present in affected individuals. Only a few cases have been described. Two mutations in the gene have been identified. One point mutation at nucleotide 413 (Arg89 to Cys) was designated DPGM Creteil I.[168] DPGM Creteil II is a deletion of nucleotide 205, inducing a frameshift and consequently leading to a premature stop codon.[94]

Glutathione Pathway

The sulfhydryl-containing tripeptide reduced glutathione (GSH) protects hemoglobin and other critical RBC proteins from peroxidative injury. In the process of reducing peroxides or oxidized protein sulfhydryl groups, GSH is converted to GSSH (oxidized glutathione). As shown in Figure 21-9, its metabolic pathway includes several enzymes.

Gamma-Glutamylcysteine Synthetase

Gamma-glutamylcysteine synthetase (GCS; EC 6.3.2.2) catalyzes the first step in glutathione biosynthesis in which glutamylcysteine is synthetized using L-glutamate, L-cysteine, and ATP. This amide linking is the rate-limiting step in glutathione synthesis. There is a feedback inhibition by glutathione. The protein is a heterodimer composed of a catalytic heavy chain (GCS_h; 636 amino acids; 73 kDa) and a regulatory light chain (GCS_l; 274 amino acids; 31 kDa).[52,53]

The gene for GCS_h *(GLCLC)* is localized on chromosome 6p12[185] and the gene for GCS_l *(GLCLR)* on chromosome 1p21.[184]

Hereditary GCS deficiency is very rare. Deficiency leads to CNSHA and drug- and infection-induced hemolytic periods. Only 10 patients to date have been described, of which 5 were characterized at the molecular level.[23,59,166] A homozygous 1109A to T (His370Leu) substitution in the GLCLC gene was found,[23] probably resulting in an unstable protein. Another study identified in two related patients a homozygous 473C-to-T substitution resulting in a leucine residue instead of proline at amino acid 158 of GCS_h.[166] Recently, two related patients were reported with a C-to-T missense mutation at nucleotide 379, encoding for a predicted Arg127Cys substitution. Computer modeling indicated the mutation to be localized in a cleft on the protein surface of GCSh.[59]

Glutathione Synthetase

Glutathione synthetase (EC 6.3.2.3; GSH-S) mediates the second step in the synthesis of GSH, by the addition of glycine to the dipeptide γ-glutamylcysteine. The protein is a homodimer of 52 kDa.[51]

The gene for GSH-S is located on chromosome 20q11.2 and contains 12 exons spanning 23 kb.[183-186]

In the few cases that have been described, mild chronic hemolytic anemia is associated with deficiency of GSH-S.[155] The disorder is inherited in an autosomal recessive mode. Such people may also have more severe acute hemolytic crises when exposed to redox substances, such as 8-aminoquinolines or other "oxidant" drugs.

There are two distinct types of GSH-S deficiency, both associated with mild chronic hemolysis; in one type, hemolysis is the only clinical manifestation.[155] In the other, the major clinical features are mental retardation, severe generalized muscle weakness, tremors, incoordination, hemolytic anemia, and metabolic acidosis. This second and much more severe type of GSH-S deficiency is also known as 5-*oxoprolinuria* or *pyroglutamic aciduria*.[186] The difference in severity of these disorders reflects the fact that in the mild form, GSH-S deficiency is confined to the RBCs because in this disorder the GSH-S is unstable. GSH-S activity is present in adequate quantity in young RBCs, but it rapidly declines as the cells age, because the cells are unable to synthesize new molecules of GHS-S. Other cells of the body that have nuclei and ribosomes can compensate for accelerated denaturation of GSH-S by synthesizing more. On the other hand, in the severe systemic form of GSH-S deficiency, all cells of the body have low activities of GSH-S because they cannot form this enzyme in adequate amounts. In both types of GSH-S deficiency, RBCs exhibit notable reduction in GSH concentration.

Several mutations in the gene have been identified recently, associated with the disease. The majority of the mutations are missense, two small deletions and one splice site mutation.[40,41,183]

Glutathione Reductase

Glutathione reductase (EC 1.8.1.7; formerly EC 1.6.4.2; GSR) links the glutathione pathway to the hexose monophosphate pathway through the reversible oxidation and reduction of NADP. Flavin adenine dinucleotide (FAD) is necessary as a cofactor. The enzyme maintains high levels of reduced glutathione in the cell. Two isoforms exist, a mitochondrial and cytoplasmic form, produced by alternative initiation.[85] The molecule is a homodimer, linked by a disulfide bridge. Each subunit (522 amino acids; 56 kDa) is divided into four domains of which domains one and two bind FAD and NADPH, respectively, and domain four forms the interface.[84,192]

The gene encoding GSR is located on chromosome 8p21.1, spans 50 kb, and contains 13 exons.[85]

Glutathione reductase deficiency (OMIM 138300) is an autosomal disease and, except when very severe, is not associated with hemolysis. The disease has been associated with drug-sensitive hemolysis and favism.[97]

Glutathione Peroxidase

Glutathione peroxidase (EC 1.11.1.9; GSH-Px) is active as a homotetrameric enzyme (subunits of 21 kDa) and effects the conversion of hydrogen peroxide to water, thus reducing peroxidative stress to proteins in the cell. Several isoforms exist, but GSH-Px1 is active in the erythrocytes. RBCs also have high catalase (EC 1.11.1.6) activity that converts H_2O_2 to water and O_2; thus GSH-Px is redundant. In fact, deficiencies of either catalase or GSH-Px are without serious consequences for the RBCs because the presence of either of these two enzymes can compensate for deficiency of the other.

Partial deficiencies of GSH-Px have been documented,[56] but a clear cause-effect relationship with hemolysis has not been established. The gene has been assigned to chromosome 3p21.3.[216]

Purine-Pyrimidine Metabolism

Pyrimidines and purines are the building blocks of DNA and RNA. In addition, they have a role in the formation of coenzymes and active intermediates in carbohydrate and phospholipid metabolism.

Controversy exists concerning the cause and effect relationships between deficiencies of the enzymes adenylate kinase (AK; EC 2.7.4.3) and adenosine triphosphatase (ATPase; EC 3.6.1.3) and hemolytic disease.[61,93] Since the consensus seems to be that there is no association, these enzymes will not be discussed here.

Pyrimidine-5′-Nucleotidase

Pyrimidine-5′-nucleotidases are a group of enzymes dephosphorylating pyrimidine nucleotides to the corresponding nucleosides. The pyrimidine bases diffuse out of the erythrocyte and the phosphates are retained. Pyrimidine phosphates are present on ribosomes of erythroblasts and reticulocytes, but there are normally no pyrimidines in mature RBCs. Two cytoplasmic forms of the enzyme were identified in the erythrocyte, P5′N-1 and P5′N-2. These enzymes are encoded by different genes and have different molecular properties and substrate specificities.[133,189] Since there are no known disorders associated with deficiency of P5′N-2, this enzyme will not be further discussed here.

Pyrimidine-5′-nucleotidase-1 (P5′N-1; uridine 5′ monophosphate hydrolase 1 (UMPH-1); EC 3.1.3.5; MW 34 kDa) is a monomeric unphosphorylated protein and drives the principal mechanism for catabolism of the ribosomal RNA. Enzyme activity is dependent on magnesium ions and has a substrate specificity for UMP, CMP, and dCMP. The tertiary structure is as yet unknown. P5′N-1 is one of the most age-sensitive RBC enzymes, and activity declines rapidly during the first days in circulation to remain stable at a low level in the mature RBC.[24]

The gene encoding P5′N-1 was only very recently identified and maps to chromosome 7p15-p14, spans about 50 kb, and consists of 10 exons. Two pseudogenes were identified on chromosomes 4 and 7. The cDNA of about 1300 base pair (bp) codes for two different proteins, one being 286 amino acids long, the other 297 amino acids.[102] The messenger is alternatively spliced. One mRNA initiates in exon 1 and continues from exon 3, exon 2 being spliced out. The transcript codes for the 286 amino acid protein, being P5′N-1. The

longer protein is transcribed from a messenger that initiates from exon 2 and continues through the exons sequentially.[163] The significance of this alternatively spliced messenger is unknown, but the process shows remarkable resemblance to the alternative initiation generating pyruvate kinase mRNA, where it drives tissue specificity (see under pyruvate kinase in this chapter).

P5′N-1 deficiency (OMIM 266120) is a relatively common cause of nonspherocytic hemolytic anemia, and, because of the relatively mild phenotypic expression, many cases might be undetected as yet.[21,65,163] The disease is inherited in an autosomal recessive manner and is the only red cell enzyme deficiency in which red cell morphology is helpful. Prominent and characteristic basophilic stippling is visible in blood films. There usually is an accumulation of high concentrations of pyrimidine nucleotides, mostly uridine triphosphate (UTP) and cytidine triphosphate (CTP), in the red cells.

After the recent identification of the gene, there have been a number of reports describing the mutations that cause P5′N-1 deficiency. To date, 23 patients have been characterized at the molecular level, identifying 14 different mutations. Four are missense, three cause aberrant splicing, two introduce a premature stop codon, and five result in a frameshift.[14,28,102,163] No relationship between the genotype and phenotype could be established.

Adenosine Deaminase

Adenosine deaminase (ADA; EC 3.5.4.4) is the enzyme of the purine metabolism that deaminates adenosine and 2′-deoxyadenosine to inosine and 2′-deoxyinosine, respectively. ADA deficiency, which leads to *severe combined immunodeficiency disease* (SCID), is associated with a decrease in RBC adenosine deaminase activity, without hemolysis. ADA deficiency will not be discussed here.

The abnormality of this enzyme associated with hereditary nonspherocytic hemolytic anemia is an increase in activity in the erythrocyte. This results in the depletion of red cell ATP and hemolysis. Few cases with a thirtyfold to seventyfold increase have been described. It is the only RBC enzymopathy that is inherited as an autosomal dominant disorder. The molecular mechanism of this disorder has not been identified. High levels of normal ADA mRNA were present, suggesting a mutation in an in cis transcriptional regulating element, which could not be identified.*

Methemoglobin Reduction

Hemoglobin can bind oxygen only in the reduced ferrous (Fe^{2+}) state. Consequently, when hemoglobin is oxidized to the ferric (Fe^{3+}) state, the capacity to bind oxygen is lost, which ultimately will lead to pathological consequences. The oxidized state of hemoglobin is called methemoglobin and is normally present at less than 1%. Thus to preserve oxygen-binding capacity, the red cell must keep hemoglobin in the reduced state, a process achieved mainly by the cytochrome b5/cytochrome b5 reductase system, which is NADH-dependent.

NADH-Cytochrome B5 Reductase

Nicotinamide adenine dinucleotide (NADH)-cytochrome b5 reductase (EC 1.6.2.2; cytb5r) uses NADH generated in the reaction in the Embden-Meyerhof pathway by glyceraldehyde 3-phosphate dehydrogenase, to reduce the 12 kDa protein cytochrome b5. Cytochrome b5 in turn reduces methemoglobin to hemoglobin.

The enzyme is present in two different forms. A membrane-bound 300 amino acid form is located mainly in the endoplasmic reticulum and outer mitochondrial membrane.[29,69,149] The membrane form has a role in desaturation and elongation of fatty acids, cholesterol biosynthesis, and drug metabolism.

The second form is a soluble protein of 275 amino acids and is RBC specific.[149] They share an identical hydrophilic C-terminal domain, but differ at the *N*-termini. The membrane form has an additional stretch of 25 hydrophobic amino acids.

Both forms of cytb5r are transcribed from the same gene on chromosome 22q 13-qtr spanning 31 kb. It contains 9 exons, but there are two exons[1] (exon 1 and [later discovered] exon 1S).[220] The soluble form is coded by exons 2 through to 9, while the longer membrane bound form is coded for by exon 1 and continues through the exons sequentially.

NADH-cytochrome b5 reductase deficiency (OMIM 250800) is an autosomal recessive disorder, causing hereditary methemoglobinemia. There are three types. In type I, the enzyme is deficient only in erythrocytes. Patients are typically blue and/or gray and cyanotic, but not very sick. Type II is more severe, the enzyme being completely deficient, causing mental retardation and neurological impairment. In type III the enzyme is deficient in all blood cells.

A total of 34 different mutations have been identified associated with cytb5r deficiency to date.[57,150] Sixteen were associated with type I and 16 with type II. These mutations were distributed over all exons, except for exons 1 and 1S.

Detection of Hereditary Red Cell Enzyme Deficiencies

Other than deficiencies of G6PD and possibly PK, RBC enzyme defects are rare; therefore it is not practical to attempt to identify them in laboratories that perform such tests only rarely. Specimens should be shipped by mail to reference laboratories that specialize in performance of these assays. As a rule, whole-blood specimens anticoagulated with EDTA are suitable and the specimens can be shipped at room temperature.[21] Exceptions are assays for phosphorylated sugar intermediates, 2,3-DPG, and nucleotide intermediates, which are unstable in freshly drawn blood and require immediate deproteinization in perchloric acid.[21]

*References 35, 37, 38, 50, 113, 151, 199.

Care must be taken to remove leukocytes and platelets in assays such as for PK, since these cells do contain PK activity, obscuring a deficiency in the red cells.

Other pitfalls in correct diagnosis of glycolytic enzyme deficiencies include the red cell age dependency of enzymes such as PK, HK, and G6PD. The measurement of these enzymes simultaneously can give an idea about red cell age and relative deficiencies. Many patients suffering from severe hemolysis have already received blood transfusions. When this occurs, interpreting results from red cell enzyme assays must be done with great care, since the presence of donor erythrocytes will obscure any deficiencies. In addition, some mutant enzymes display a normal activity in vitro, while in vivo severe hemolysis can occur. More sophisticated assays to measure, for example, heat instability and kinetics have to be used in those cases.

In the last few years, the genes coding for the red cell enzymes have been localized and characterized. This made molecular diagnostics possible, and many causative mutations have been identified. Molecular diagnostics at the DNA and RNA level is very attractive in situations in which the diagnosis of enzyme deficiency is difficult or impossible by activity measurements, such as in transfused patients, as explained above. In addition, prenatal diagnosis is now available. The ability to study the effects of mutations in three-dimentional computer models of the enzymes and the opportunity to express mutant enzymes, will provide a better understanding of the genotype-phenotype relations in these hemolytic disorders.

Methodology

In this section, methodological principles and reference values are given for several of the methods used to measure red cell enzymes. Methodological details of these methods are given in the Evolve site that accompanies this book at http://evolve.elsevier.com/Tietz/textbook.

Method for the Determination of Glucose-6-Phosphate Dehydrogenase

Principle

Glucose-6-phosphate dehydrogenase (G6PD) catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconate with a concurrent conversion of $NADP^+$ to NADPH. The activity of G6PD is determined by measurement of the rate of increase of NADPH concentration. Whereas $NADP^+$ is transparent to ultraviolet (UV) light, NADPH strongly absorbs UV light. Therefore the rate of increase in absorbance at 340 nm is the measure of enzyme activity.

Reference Intervals

The reference interval for G6PD in erythrocytes is 8-14 U/g Hb. Values greater than 18 U/g Hb are often encountered in any condition associated with younger than normal RBCs (as in hemolytic anemias not due to G6PD deficiency) but are of no clinical significance.

Method for Screening Erythrocytes for Glucose-6-Phosphate Dehydrogenase Deficiency

In this screening test, $NADP^+$ is reduced to NADPH in both the G6PD and the 6PGD reactions of the hexose monophosphate pathway. If G6PD activity is low, only a small quantity of NADPH is formed. This is reoxidized to $NADP^+$ by glutathione reductase present in RBCs, and no fluorescence is observed. In the presence of adequate amounts of G6PD, the rate of reduction of $NADP^+$ substantially exceeds the rate of oxidation of NADPH by glutathione reductase, and enough NADPH accumulates in RBCs to be demonstrable by its fluorescence.

Method for the Determination of Pyruvate Kinase Activity

Principle

In this assay, the PK reaction is linked with the LD reaction in which NADH is oxidized to NAD^+.

$$\text{Phosphoenolpyruvate} + \text{ADP} \xrightarrow{\text{PK}} \text{pyruvate} + \text{ATP}$$

$$\text{Pyruvate} + \text{NADH} \xrightarrow{\text{LD}} \text{lactate} + \text{NAD}^+ + \text{H}^+$$

Because LD is present in excess, the rate of NADH oxidation is limited by the activity of PK. The reaction rate is measured by the rate of decrease in absorbance at 340 nm. Assays are performed at low substrate concentration with and without the addition of fructose-1,6-diphosphate, because some PK variants associated with hemolysis have atypical reaction kinetics (and thus may exhibit "normal" activity at high substrate concentrations but lower than normal activity at lower substrate concentrations) or may show absence of enhancement by fructose-1,6-diphosphate, the allosteric activator of PK.

Reference Intervals

Reference intervals for pyruvate kinase are:
High substrate 9 to 16 U/g of Hb
Low substrate 1.7 to 6.8 U/g of Hb.

Method for the Determination of Glucose Phosphate Isomerase Activity

Deficiency of glucose phosphate isomerase (GPI) has been associated with chronic hemolytic disease in a few dozen reported cases and may also cause hemolytic disease of the newborn. Although the third most frequently reported enzymopathy causing hemolytic disease, it has been quite rare in our experience.

Principle

GPI catalyzes the interconversion of G6P and F6P:

$$\text{F-6-P} \xleftrightarrow{\text{GPI}} \text{G-6-P}$$

$$\text{NAPH}^+ + \text{G-6-P} \xleftrightarrow{\text{G-6-PD}} \text{6-phosphogluconate} + \text{NADPH} + \text{H}^+$$

In this assay, F6P is used as the substrate for GPI. The GPI reaction is linked to the G6PD reaction. The rate of reduction of $NADP^+$, as indicated by the increase in absorbance at 340 nm, is the measure of GPI activity.

Reference Intervals

The reference interval for GPI is 50-70 U/g Hb.

Method for the Determination of Erythrocyte Glutathione Concentration

Erythrocyte GSH concentration is diminished in many people who have defects in the hexose monophosphate or GSH synthesis pathways. The GSH stability test, originally devised to permit identification of people susceptible to hemolysis from primaquine (later shown to be the result of G6PD deficiency), still remains a useful "stress test" of the intactness of these closely linked pathways. Because deficiencies of GSH synthetase and γ-glutamyl cysteine synthetase are rare disorders, it is not practical for clinical laboratories to contemplate assays for these enzymes unless results of the easily performed GSH stability test are abnormal.

Principle

Virtually all of the nonprotein sulfhydryl groups of RBCs are in the form of reduced GSH. 5,5′-Dithiobis(2-nitrobenzoic acid) (DTNB) is a disulfide chromogen that is readily reduced by sulfhydryl compounds to an intensely yellow compound. The absorbance of the reduced chromogen is measured at 412 nm and is directly proportional to the GSH concentration.

Reference Interval

The reference interval for GSH is 5.5-7.5 μmol/g Hb.

Method for Screening for Deficiency of Pyrimidine-5′-Nucleotidase Activity

Principle

Pyrimidine-5′-nucleotidase effects the release of phosphate from cytidine-5′-monophosphate and uridine-5′-monophosphate and thus is an enzyme involved in the catabolism of RNA. RNA is a normal constituent of reticulocytes but not of mature RBCs. In the absence (or notable deficiency) of P-5′-N, RNA persists in RBCs and is manifested by striking basophilic stippling and mild to moderate hemolytic anemia.

Pyrimidine nucleotides, extracted with acid from the RNA remaining in P-5′-N-deficient RBCs, have an absorption peak at 270 nm. This peak is quite distinct from the peak at 257 nm, which is because of purine nucleotides (such as ATP) that are normally present. When P-5′-N is deficient and RNA persists, the P-5′-N deficiency can be inferred by observing a pyrimidine nucleotide peak at 270 nm in an acid extract of RBCs.

Reference Intervals

In normal specimens or in those of any disorder but P-5′-N deficiency, there is an absorbance curve of low amplitude with a peak at about 257 nm, this being caused by the presence of purines, such as ATP and ADP. No peak is seen at 270 nm. In P-5′-N deficiency, a notably higher-amplitude curve is observed, with a peak at 270 nm. The absorbance maximum for normal RBCs is 257 nm, and the observed absorbance value is approximately 0.3/108 RBCs per milliliter. In P-5′-N deficiency, the peak absorbance is at 270 nm, with absorbance values of approximately 0.8/108 RBCs per milliliter having been observed. No interfering substances are known.

Method for the Determination of 2,3-Diphosphoglycerate in Erythrocytes

This enzyme is the predominant glycolytic intermediate of RBCs and has a vital role in modulating the affinity of hemoglobin for O_2.

Principle

The assay of 2,3-DPG is based on an equilibrium system between 3-phosphoglycerate, 2-phosphoglycerate, and PEP when monophosphoglycerate mutase (MPGM) and enolase are present.

$$\text{3-phosphoglycerate} \underset{\text{2,3-DPG}}{\overset{\text{MPGM}}{\rightleftharpoons}} 2$$

$$\text{3-phosphoglycerate} \overset{\text{enolase}}{\rightleftharpoons} \text{PEP}$$

The addition of 2,3-DPG (in the sample) shifts the equilibrium so that more 2-phosphoglycerate is converted to 3-phosphoglycerate. This in turn results in the conversion of PEP to 2-phosphoglycerate. The rate of decrease in PEP concentration is measured by the decrease in absorbance at 240 nm, which is proportional to the amount of 2,3-DPG in the specimen.

Reference Intervals

The mean (SD) 2,3-DPG is 12.3 (1.87) μmol/g Hb [0.79 (0.12) mol/mol Hb] or 356 (54) μmol/1012 RBCs [356 (54) amol/RBC].

CHAPTER 22

Cytokines

Manuel Santos Rosa, Ph.D.,
*and Anabela Mota Pinto, Ph.D.**

Cytokines are peptides used by cells for intercellular communication and for controlling the inner environment of the cells in which they operate.[30,576] They are produced by cell types that have important roles in the immune response, inflammation, hemopoiesis, healing, and systemic response to injury. Many cytokines are measured by bioassay and immunoassay.[212]

This chapter begins with a background discussion of cytokines followed by discussions of some important cytokines. The chapter concludes with a discussion of the analytical aspects of cytokine measurement.

BACKGROUND INFORMATION

History

The evolution of cytokines as molecules of major biological significance[437] can be divided into four different periods—each is characterized by different technical capacities and scientific purposes.[1,526] For example, initial studies in the 1950s to the 1970s identified a number of cellular protein molecules that had specific functions. Cohen and others[94] first suggested the word "cytokine" to describe these molecules. In the 1970s several cytokines were partially purified and characterized, and specific antibodies against them were produced. The 1980s are considered by many to be the golden age of cytokine research because many individual cytokines were discovered and cloned and specific monoclonal antibodies against them produced. In the 1990s new genetic techniques (e.g., gene knockout and transgenic animals) were developed that led to a better understanding of the biological roles of cytokines and to the production and availability of large amounts of recombinant cytokines for use in therapeutic trials. The development of this deoxyribonucleic acid (DNA) technology has produced evidence for a large number of defined peptides that carry signals for activity, growth, and differentiation of a wide variety of cells.

Initially four groups of molecules were distinguished by either their biological function or by the origin of their scientific discovery.[526] They include (1) lymphocyte-derived proteins (lymphokines and monocyte-derived proteins [monokines]); (2) antiviral interferons (IFNs) and agents; (3) hematopoietic growth factors (colony stimulating factors); and (4) nonhematopoietic growth factors. However, it was quickly found that a redundancy of function occurred both within and between those groups. This led to the view that these molecules act in a network, and their individual functions are often difficult to assess in vivo. Ongoing studies continue to discover and identify additional molecules involved in the communication between cells, and it is now known that we are dealing with a wider and more heterogeneous group of molecules than was once supposed.

Rationale for Measurement

Cytokines are increasingly being measured for clinical applications.[212] Reasons for doing so include:

1. Cytokines are directly implicated in various pathophysiological conditions in humans, and their increased production is responsible for their elevated levels in different body fluids, including blood, synovial fluid, cerebrospinal fluid, amniotic fluid, and bronchoalveolar lavage fluid.
2. Cytokine concentrations reflect the severity of some diseases and are markers of prognosis. This is particularly applicable for infectious diseases (bacterial sepsis and parasitological infections) and immune disorders (autoimmune diseases, such as rheumatoid arthritis[88] and systemic lupus erythematosus, and allergic diseases, such as asthma and skin hypersensitivity).

*The authors gratefully acknowledge the contributions by Drs. Jacques Bienvenu and John Whicher on which portions of this chapter are based.

TABLE 22-1 Cytokines and Their Designations (Abbreviations)

BDNF	Brain-derived neurotrophic factor
CKs	**Chemokines***
CNTF	Ciliary neurotrophic factor
EGF	Epidermal growth factor
Epo	Erythropoietin
FGF	Fibroblast growth factor
FLt3L	Fetal liver tyrosine kinase 3
G-CSF	Granulocyte colony stimulating factor
GM-CSF	Granulocyte-macrophage colony–stimulating factor
IFNα	Interferon α (type I interferon)
IFNβ	Interferon β (type I interferon)
IFNγ	Interferon γ (type II interferon)
IGF	Insulin-like growth factor
IL-1 to IL-18	**Interleukins 1 to 18**
LIF	Leukemia inhibitory factor
M-CSF	Monocyte/macrophage colony stimulating factor
MIF	Migration inhibition factor
NGF	Nerve growth factor
NT-3, NT-4	Neurotrophin-3, neurotrophin-4
OSM	Oncostatin M
PDGF	Platelet-derived growth factor
SCF	Stem cell factor
TGFα	Transforming growth factor α
TGFβ	Transforming growth factor β
TNFα	Tumor necrosis factor α
TNFβ	Tumor necrosis factor β
TPO	Thrombopoietin
VEGF	Vascular endothelial growth factor

*Highlighted cytokines are individually discussed later in the chapter.

3. Clinical trials involving antiinflammatory cytokines or cytokine inhibitors (anticytokines, monoclonal antibodies, and soluble receptors) require the monitoring of cytokines during the course of these treatments.
4. Kits for cytokines quantification are commercially available.

General Characteristics

Many of the more important cytokines are listed in Table 22-1. Most of these have multiple effects as demonstrated by the multiplicity and diversity of effects that they elicit. These effects depend on the responding cell type, biological network, and assay system in use.[472] Also the same molecule produced from different cells may exert a completely different biological action that may be opposite or even unrelated. In fact, the biological activity originally attributed to one cytokine may now be shown to be shared by several different molecules (redundancy), leading to the concept that very few individual cytokines are essential for basic cellular function. For example, knockout animals—lacking a specific cytokine gene—have only subtle abnormalities in their immunoinflammatory reaction. Biological networks are dependent on the influence of one cytokine on the synthesis of other cytokines (positive or negative regulatory mechanisms on cytokine cascades) and on biological activity (enhancing, suppressing, or synergic effects). This leads to modulation mechanisms often connected to the outcome of beneficial or harmful biological effects from a particular pathological event.

The functional modulation of the effect of cytokines requires the presence of cellular and soluble receptors. The expression of these receptors is regulated by specific signals, often dependent on cytokine networks. Transiently produced and of short half-life, cytokines are typically not stored as preformed molecules, and their production is dependent on transient genetic transcriptional activation and short-lived messenger ribonucleic acid (mRNA). Cytokines are rapidly secreted, leading to a brief burst of cytokine release. This burst is very important for cytokines to achieve distant activities, contrasting with the small amount of these molecules necessary for local functions (see later section on interleukin-1).

Biologically, many cytokines have what appears to be an endocrine function, especially when they are released in large quantities. They also exhibit autocrine and paracrine functions because they usually have a short radius of action (Figure 22-1). However, there is an enormous difference between these molecules and the hormones. For example, hormones are produced continuously, although with variation in concentration, and cytokines are usually produced only after the action of an activation signal and for other reasons previously mentioned. In addition, the receptors for cytokines are often of high affinity but are expressed with a low density on cell membranes.

Nomenclature

Cytokines are difficult to define because they encompass different families of molecules with regulatory functions that operate on receptors and are linked only by common biological actions. Here, we define cytokines as low molecular weight proteins (often glycosylated), with a cellular regulatory action, that are produced by different cells and operating preferentially in the immunoinflammatory response. Physiologically, cytokines (1) are produced by and operate on different types of cells, (2) act locally or at a distance, (3) operate in a network, and (4) are repressed or modified by various mechanisms (Figure 22-2).

Classification

Because cytokines were discovered in several different scientific disciplines and are functionally diverse—their classification, like their definition—has been exceedingly difficult.[319] However, they have been classified by their (1) function (Box 22-1),[1,432,436] (2) family group (Box 22-2),[152,421,472,485] and (3) physiochemical structure (Table

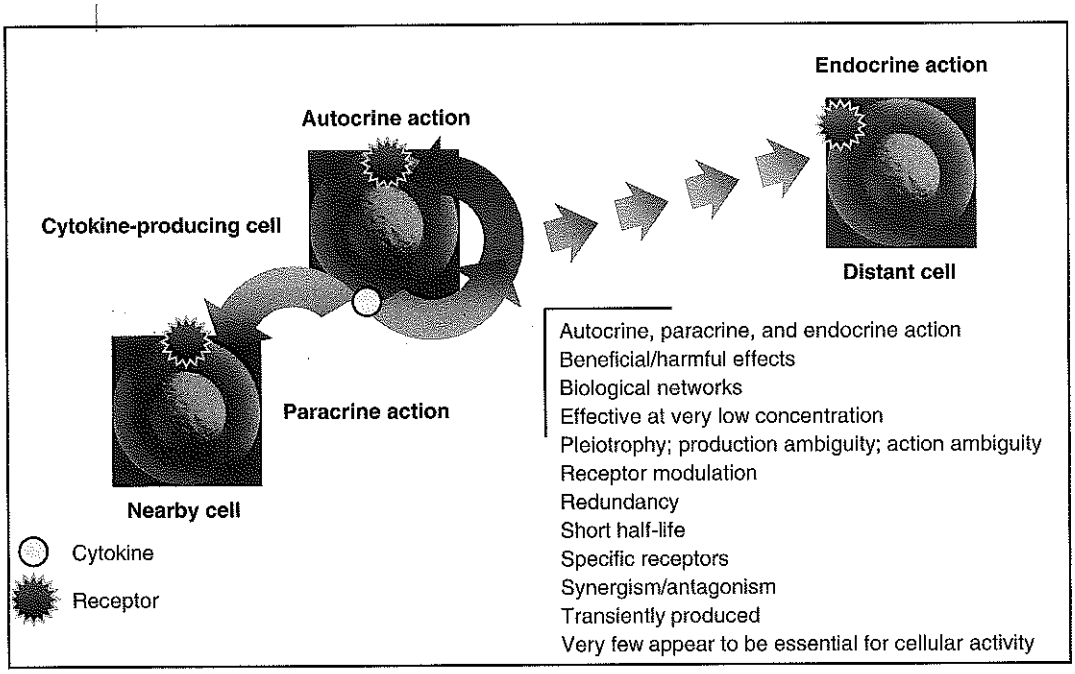

Figure 22-1 Principal functional characteristics of cytokines.

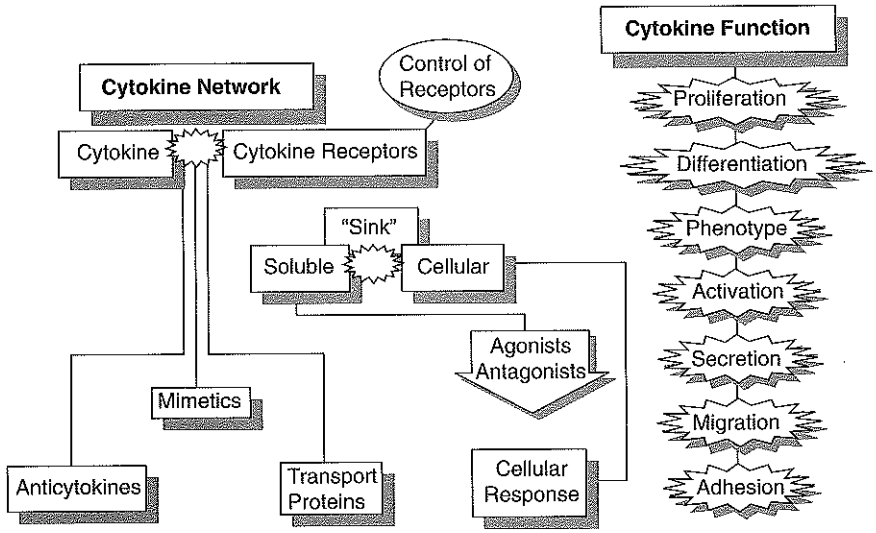

Figure 22-2 Cytokine network and generic function over cells.

22-2).[341,389] Currently, from a practical viewpoint, cytokines are classified as belonging to (1) hemopoietin, (2) interferon, (3) tumor necrosis factor (TNF), or (4) chemokine families.

BIOCHEMISTRY

Cytokines have very stable structures with the presence of carbohydrates and disulfide bonds imparting solubility, stability, and resistance to cleavage. Despite the lack of amino acid sequence similarity, the limited variation in their overall three-dimensional structure may reflect the evolutionary origins of cytokines. This structural variation has made possible the definition of at least the following four different structural families.[389]

Four-α-Helical Bundles

Molecules having this structure constitute the largest family of cytokines. These molecules have an antiparallel four-α-helical bundle structure (A, B, C, and D helices, A-D and B-C helix pairs). The A-D helix pair frequently represents the region that interacts with the appropriate receptors.

This family includes two subtypes:

1. Short-chain (Sc subtype): interleukin (IL)-2, IL-3, IL-4, IL-5, IL-7, IL-9, IL-13, granulocyte-macrophage colony–stimulating factor (GM-CSF), monocyte/macrophage colony–stimulating factor (M-CSF), stem cell factor (SCF), IFNγ

BOX 22-1 Classification of Cytokines by Function[1]

Cytokines That Mediate Natural Immunity
Type I IFN
TNF
IL-1, IL-6
Chemokines

Cytokines That Regulate Lymphocyte Activation, Growth, and Differentiation
IL-2
IL-4
TGFβ

Cytokines That Regulate Immune-Mediated Inflammation
IFNγ
Lymphotoxin
IL-5, IL-10, IL-12
Migration inhibition factor (MIF)

Cytokines That Stimulate Hematopoiesis
C-Kit ligand
IL-3, IL-7
GM-CSF, M-CSF, G-CSF, other CSFs

BOX 22-2 Elgert's Classification of Cytokines by Family Group[152]

Interleukins: IL-1α, IL-1β, IL-2 to IL-15
Chemokines: IL-8, MCP-1
Interferons: IFNα, IFNβ, IFNγ
Cytotoxic/immunomodulatory/growth factors: TNFβ, TNFα, TGFβ
Colony stimulating factors: G-CSF, GM-CSF, IL-3, IL-7, M-CSF

2. Long-chain (Lc subtype): IL-6, IL-12, Epo, granulocyte colony–stimulating factor (G-CSF), leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), IL-11, GH, IFNα, IFNβ, IL-10

The Sc subtype has a general oblate ellipsoid shape and the Lc subtype an overall elongated cylindrical shape.

Short-Chain α/β Structures

This family has three subfamilies:

1. The epidermal growth factor (EGF) subfamily of cytokines produced as large transmembranar precursor molecules containing at least one EGF domain in the extracellular region. This domain consists of at least two antiparallel β-strands connected to the intervening loops by three disulfide bonds.
2. The chemokine (CK) subfamily of cytokines with a general conformation of an open-face β-sandwich with a C-terminal α-helical segment, divided into three major subgroups based on the amino acid sequence around the conserved cysteine residues.
3. The insulin-related subfamily of cytokines consisting of a conserved set of three disulfide bonds that link three short α-helices.

Long-Chain β-Sheet Structures

This family has three subfamilies:

1. The TNF subfamily of cytokines (TNFα, TNFβ, CD27, and Fas ligand). The members of this subfamily are often cell surface–associated symmetrical homotrimers of which subunits have a conformation of β-jelly rolls. The homotrimer is cone shaped, which may explain the inactivity of isolated monomers and the symmetry of three receptor subunits interacting with the TNF trimer.
2. The IL-1 and the fibroblast growth factor (FGF) subfamilies of cytokines. These molecules adopt a β-trefoil fold, which consists of 12 strands of β-sheet forming six hairpins. They are synthesized with no leader sequence

TABLE 22-2 Classification by Physicochemical Structure of Cytokines and Their Receptors[341,389]

Cytokine	Cytokine Structure	Receptor-Specific Component	Shared Chain
IL-2	6-α-helical short chain	Hemopoietin domain	Common $\bar{\omega}$
IL-4, IL-7, IL-9, IL-13, IL-15	4-α-helical short chain	Hemopoietin domain	Common γ
IL-3, IL-5, GM-CSF	4-α-helical short chain	Hemopoietin domain	Common β
IFNγ	4-α-helical short chain	IFNγR	—
IL-6, IL-11	4-α-helical long chain	Hemopoietin domain	gp130
G-CSF	4α-helical long chain	—	G-CSF-R
TGFβ	β-sheet	Serine/threonine kinase	—
IL-1 α, IL-1β	β-sheet	Ig-like	—
TNFα, TNFβ, CD40L, CD27L, FASL	β-sheet	TNF p75, p55	—
Chemokines	—	Rhodopsin	—

(unlike most other cytokines), and their mechanism of secretion remains unclear.

3. The platelet-derived growth factor (PDGF), transforming growth factor β (TGFβ), and nerve growth factor (NGF) subfamilies of cytokines show β-sheet–rich structures known as cystine knots, which are characterized by an interlocking set of three disulfide bridges and at least four segments of twisted antiparallel β-sheets corresponding to an elongated asymmetric monomer. Usually, each of these growth factors forms a homodimeric complex with a different orientation of the monomers in each type of homodimer.

Mosaic Structures

This family is more heterogeneous than the other three, with diverse members such as heregulins or neuregulins, glial growth factor (GGF), hepatocyte growth factor (HGF), and IL-12.

The heregulins are cell surface proteins with both an EGF and an immunoglobulin (Ig)-like domain on the extracellular side of the molecule; GGF has both an EGF domain and a kringle domain. HGF is a heterodimer with the α-subunit containing four kringle domains (typical of plasminogen) and the β-subunit having homology to serine proteases. IL-12 is a heterodimer with the α-subunit similar to the long-chain, four-α-helical bundle cytokines and the β-subunit overlapping the complementary hemopoietin domain receptor.

Cytokine Receptors

Cytokine receptors represent the functional link between cytokines and target cells and the resultant biological action.

Studies have shown them to be structurally very heterogeneous, and generally confined to five main families of proteins (Table 22-3).

TABLE 22-3 Cytokine Receptor Families and Their Cytokines

Cytokine Receptor Family	Cytokines
Immunoglobulin superfamily	IL-1, M-CSF, C-kit
Class I cytokine receptors (hematopoietin)	IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-13, IL-15, G-CSF, GM-CSF, OSM, LIF, CNTF, growth hormone, prolactin
Class II cytokine receptors (Interferon)	IFNα, IFNβ, IFNγ, IL-10
TNF receptors	TNFa, TNFb, CD40, NGF, FAS
Chemokine receptors	Chemokines

The most important receptors for the immunoinflammatory response are the Class I and Class II receptors; however, the TNF and the chemokine receptors also are biologically important. The Class I and Class II receptors share some characteristics, such as having multiple subunits—one that binds the cytokine and another that mediates signal transduction—with tyrosine phosphorylation of the receptor occurring through the activity of protein tyrosine kinases. The Class I cytokine receptors bind the largest number of cytokines associated with immuno- and hematopoietic systems and are divided into three receptor subfamilies with identical signal-transduction subunits. However, this subunit is shared by different cytokines, explaining the redundancy and antagonism exhibited by some of these molecules. The three subfamilies are the (1) common β-subunit(receptor for GM-CSF, IL-3, and IL-5), (2) common gp130 subunit (receptor for IL-6, IL-11, CNTF, and LIF/OSM), and (3) common γ-subunit (receptor for IL-2, IL-15, as heterotrimers; IL-7, IL-9, and IL-4, as classical two-subunit receptors with a common γ-chain).

Clinical Significance

Because of their diverse biological functions, cytokines have been implicated in a number of pathological conditions, including the inflammatory process and cancer. The clinical significance of individual cytokines is discussed below.

Cytokines and the Inflammatory Process

The immunoinflammatory system is a complex network of cells and humoral elements that includes many cytokines (Figure 22-3). Typically an immunoinflammatory response is triggered by an antigen. The antigen is presented by specialized cells termed antigen-presenting cells (APCs), which present the antigen through either class I or II restrictions of the major histocompatibility complex (MHC). In the case of class I restriction, molecules of antigen are presented to CD8 T lymphocytes. In class II restriction, molecules of antigen are presented to CD4 T lymphocytes (usually referred to as "helpers"). In addition, molecules of antigen can be presented by B lymphocytes (CD19) or can present directly to Tγδ lymphocytes, with a consequent cytotoxic and cytolytical response.[475]

After antigenic presentation to CD4 and CD8 cells, there is a set of effects on other lymphocytes in which the suppressive ability on the proliferation of B lymphocytes is enhanced through CD8 cells. This prevents them from becoming plasma cells and ensures that they produce antibodies. In the case of CD4 (as classical "helpers"), they stimulate B lymphocytes and consequently their conversion into plasma cells and the production of antibodies.

CD4 lymphocytes have two subtypes: T helper (Th)1 and Th2 (Figure 22-4). Th2 is the common CD4 "helper" that "helps" B lymphocytes to be transformed into plasma cells, leading to the production of antibodies. Th1 lymphocytes are implied in a cytotoxic and cytolytical process similar to that developed by CD8 cells, which are not only classical sup-

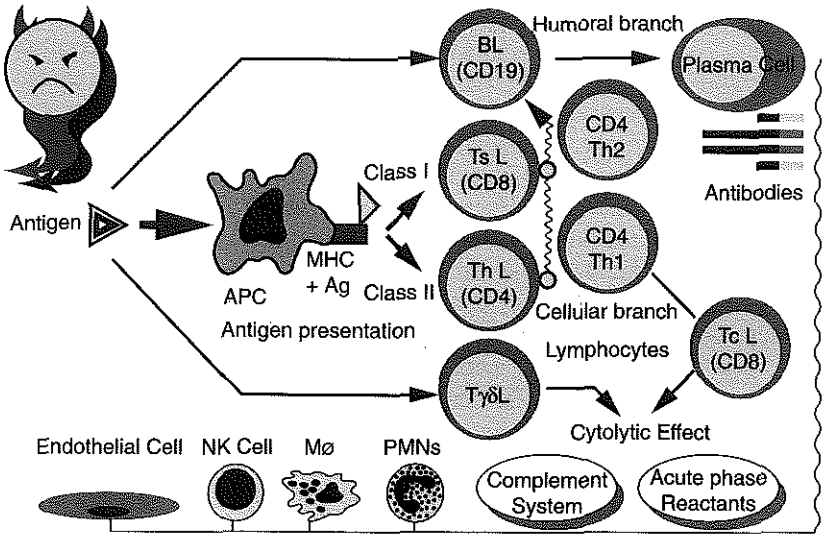

Figure 22-3 Role of cytokines in the immunoinflammatory response.

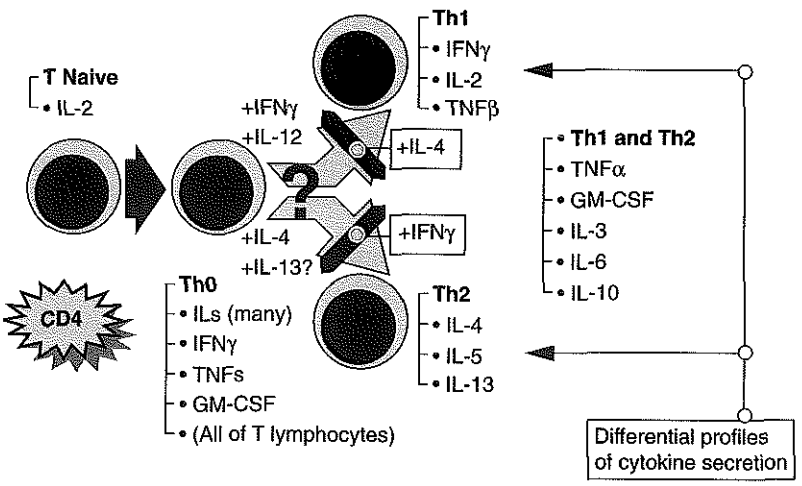

Figure 22-4 Role of cytokines in the polarization of CD4 lymphocytes.

pressors of B lymphocytes but also have cytotoxic ability. Therefore they have an essential role in the cellular polarization, leading to either cytotoxicity or the production of antibodies. The differentiation of Th1 and Th2 cells is based on the local microenvironment of cytokines. Cascades of cytokines are always present during the interactions between antigen-presenting cells and lymphocytes and also in CD4 Th1 and Th2 polarization.

In addition to the lymphocytes, many other cells participate in the immunoinflammatory process, including endothelial cells, natural killer (NK) cells, and macrophages. The complement system and the acute phase proteins are also involved in the amplification of the inflammatory process.

The transformation of CD4 lymphocytes into Th1 or Th2 subtypes is currently thought to be the central stage of the immune response (see Figure 22-4). These cells can polarize into Th1 or Th2 cells according to the cytokines contained in the microenvironment in which the cells are stimulated. For example, in an environment rich in IFNγ and IL-12, there is a Th1 polarization, and in an environment rich in IL-4 (and eventually IL-13), there is Th2 polarization. The kind of cytokine environment reciprocally inhibits the other transformation (i.e., IL-4 blocks the Th1 transformation and IFNγ blocks Th2 transformation).

When CD4 lymphocytes are transformed into Th1 or Th2 subtypes, they produce a characteristic cytokine profile (Figure 22-5) that includes IFNγ, IL-2, and TNFβ for Th1 and IL-4, IL-5, and IL-13 for Th2. TNF, GM-CSF, IL-3, IL-6, and IL-10 are common to both types of cells.

Figure 22-6 represents a general scheme of the development of human CD4 Th1 cells. Typically, there is Th1 polarization when antigenic stimulation is caused by a virus or intracellular bacteria (intracellular pathogen) followed by antigenic presentation from specialized cells such as dendritic cells, with a high production of IFNα and IL-12. The activation of NK cells then creates a high concentration of IFNγ without an increase in levels of IL-4. Thus an environ-

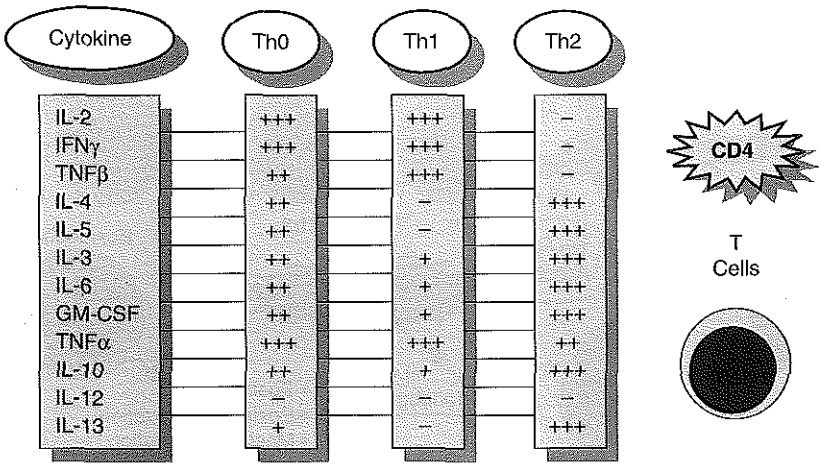

Figure 22-5 Secretion profiles of cytokines from human CD4 T cells. (See Table 22-1 for identification of cytokines.)

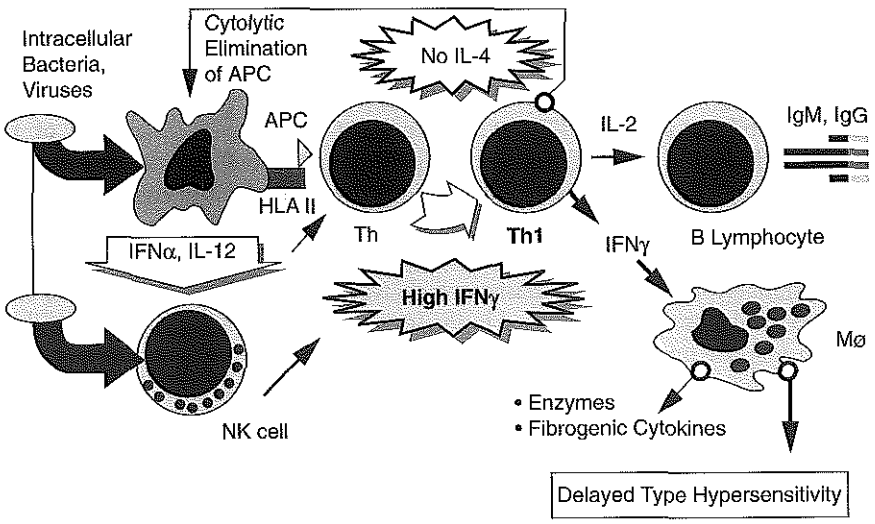

Figure 22-6 Preferential development of human CD4 Th1 cells.

ment rich in IFNγ and poor in IL-4 causes Th1 polarization, which induces a low production of antibodies (usually IgG and IgM). It also causes a cytokine-induced stimulation of phagocytic cells, such as macrophages and polymorphonuclear neutrophils (PMNs) with enzyme and cytokine release boosting the inflammatory reaction. This kind of response is the classic delayed type of hypersensitivity, which is very important for an effective response to intracellular pathogens.[42,316]

Figure 22-7 summarizes the Th2 polarization, which usually occurs because of antigenic stimulation by allergens or extracellular antigens like helminthic (parasite) antigens. This stimulation is associated with a lack of IL-12 and IFNγ production by APCs and the absence of NK activation. However, it is dependent on mast cells and basophils, which are involved in IL-4 synthesis. Thus there is an environment rich in IL-4 (increased by the spontaneous endogenous production of this cytokine) and poor in IFNγ.

An important Th2 cell-specific transcription factor is c-maf, which promotes the differentiation of Th2 cells mainly by an IL-4–dependent mechanism. It remains unclear whether c-maf possesses any IL-4–independent function in regulating the production of Th2 cytokines; c-maf, independent of IL-4, is essential for normal induction of the IL-2 receptor (IL-2R) α (CD25) in developing Th2 cells. The levels of CD25 are remarkably higher in developing Th2 cells than in developing Th1 cells during in vitro differentiation. In addition, timely blockade of IL-2–receptor signaling selectively inhibits the production of Th2 cytokines, but not IFNγ or IL-2. Taken together, they uncover an IL-4–independent and CD25-mediated function of c-maf in promoting the production of Th2 cytokines.[324] Th2 polarization then causes stimulation of B lymphocytes and the production of all classes of Igs (particularly IgE). There is also the stimulation of eosinophils, namely by IL-5, with activation and proliferation of these cells useful against parasitic infections. This kind of response (especially through the high production of IgE) is commonly called the immediate type of hypersensitivity and is associated with atopy.[103,200,264,496]

Cytokines that stimulate the innate immune response are not constitutively expressed but must be induced to function

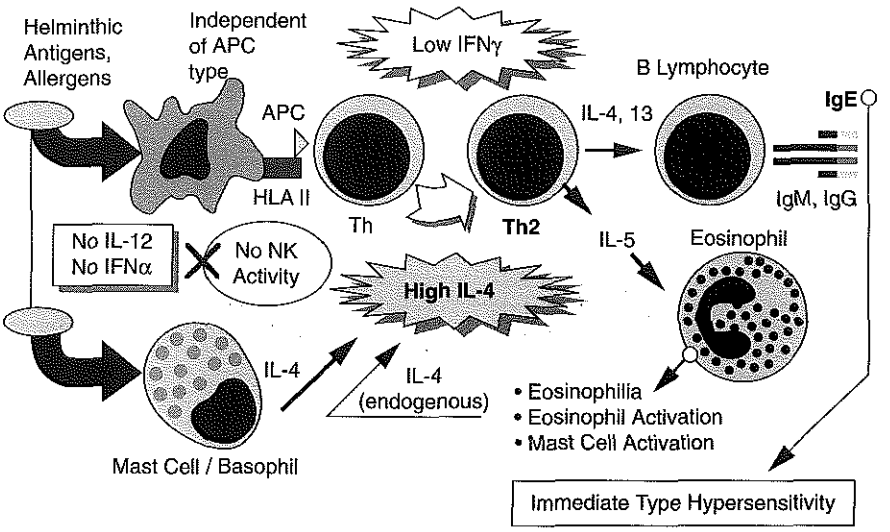

Figure 22-7 Preferential development of human CD4 Th2 cells.

by specific signals that alert the host to invading microorganisms. Toll-like receptors (TLRs) are important signaling receptors in innate host defense with a signal-transduction pathway via a MyD88-dependent pathway, which ultimately involves the nuclear factor-κB (NF-κB) family of transcriptional factors that are involved in proinflammatory cytokine expression. NF-κB serves as a master switch, transactivating various cytokines that are involved in the innate and transition to adaptive immunity: IL-1, IL-6, and IL-8. In addition, TLR4 signal transduction and NF-κB transactivation induces expression of IL-12 p40 and CD80 and CD86, which are co-stimulatory molecules that link innate and adaptive immune responses by activating antigen-specific responses by naive T cells.[414,499] Measurement of the activation of NF-κB may help to predict the outcome of sepsis, for example.[14]

Subsequent findings indicate that cytokines—in part mediators of this "overwhelming" inflammatory reaction, may also stimulate bacterial growth, impair bacterial clearance, and promote the subsequent development of nosocomial infections—may have important implications for the management of the inflammatory syndromes, such as the acute lung injury and/or acute respiratory distress syndrome patient. The interaction between cytokines and bacteria may be an important factor in the development of organ injury and death from severe infections, although numerous host and local factors, including inflammatory cells, profoundly influence the role of a specific cytokine.[130,271,458]

Cytokines regulate activation, differentiation, growth, death, and acquisition of effector functions of various cell types.[246] As a result they are increasingly recognized as important factors in the pathophysiology of chronic heart failure. Inflammatory cytokines may modulate cardiovascular functions by a variety of mechanisms. Cytokines such as TNFα and IL-1β have been shown to depress myocardial contractility. This may be due to the uncoupling of β-adrenergic signaling, an increase in cardiac nitric oxide, or alterations in intracellular calcium homeostasis. TNFα and members of the IL-6 family may also induce structural changes in the failing myocardium, such as cardiomyocyte hypertrophy and interstitial fibrosis. Additionally, TNFα and IL-1β may promote cardiomyocyte apoptosis and activate metalloproteinases and impair the expression of their inhibitors, possibly contributing to cardiac remodeling.[115]

In 2004 Okun and colleagues studied the role of cytokines and growth hormone in the regulation of sleep and narcolepsy. Collectively, proinflammatory cytokines and human growth hormone (HGH), were found to be possibly involved in the development of or the exacerbation of narcolepsy (a disabling neurological sleep disorder characterized by excessive daytime sleepiness and abnormal sleep manifestations). As the role of the immune system in sleep becomes clearer, a better interpretation will be available to assess why narcoleptics have altered cytokine and HGH levels. Future studies should be conducted to fully characterize the sources, patterns, and significance of alterations in patterns of proinflammatory cytokines and HGH in narcolepsy.[397]

Cytokines and Cancer

Cytokines have assumed an increasing importance in cancer biology since the early observations in 1893 of William Coley, who showed that a variety of malignant tumors regressed following infection with certain bacteria. The cytokine revolution of the 1970s led to the supposition that the reasons for this were the release by bacterial endotoxin of tumor inhibitory cytokines, such as the IFNs and TNFs. It is now known that cytokines are involved in the malignant process in a number of ways.

Cancers are a very heterogeneous group of diseases, and the mechanisms of malignant transformation and continuation are very diverse in different tumors; nonetheless, they represent diseases in which intercellular signaling mechanisms have been damaged so as to remove the normal constraints on cellular growth and replication. In many cases,

cytokines form part of these control mechanisms or induce other molecules that perform these functions. For example, some proto-oncogenes and oncogenes code for normal or abnormal components of cytokine receptor or signal transduction pathways.

Cytokines may have growth inhibitory properties directly on cancer cells, cause tumor regression because of modification of the host tumor relationship, or enhance antitumor immune effects. They may also act as growth factors for malignant cells, and thus therapeutic strategies to inhibit their action become possible. They may also mediate paraneoplastic effects.

Cytokine-provided survival signals are known to suppress apoptosis through inhibition of mitochondrial pathways that involve Bcl-2 family members. It was also discovered that IFNγ-TNFα synergism, rather than the Fas ligand as currently believed, is responsible for the apoptosis in cancer cell deaths.[307]

In hematopoietic cells, cytokines also regulate death receptor–mediated pathways. Hematopoietic cytokines, such as IL-3 and erythropoietin in normal cells and BCR-ABL oncoprotein in transformed cells, inhibit transcription of tumor necrosis factor–related apoptosis-inducing ligand (TRAIL). The inhibition of TRAIL function is sufficient to partially rescue cytokine-deprived cells from apoptosis. Cytokine and BCR-ABL suppression of TRAIL transcription is mediated through phosphorylation and inhibition of the forkhead FOXO3a transcription factor. BCR-ABL-induced inhibition of TRAIL transcription in hematopoietic cells may provide a novel mechanism for tumorigenicity in chronic myeloid leukemia.[188]

From the perspective of the clinical laboratory, the measurement of cytokines in biological fluids may be useful for monitoring progression of some tumors and for therapeutic monitoring when they are used as anticancer agents.

Regulation of Growth and Differentiation

Because of their growth inhibitory properties, IFNs have assumed great importance in the search for tumor-modifying cytokines. In addition, they can down regulate the expression of cellular proto-oncogenes, such as *myc*, the enzymes associated with DNA replication, and the receptors for growth factors, such as EGF. They may also activate cytotoxic T cells in vivo.

The therapeutic use of IFNα has been evaluated in many clinical trials and it has received approval from the U.S. Food and Drug Administration for use in hairy cell leukemia (HCL), the myeloid leukemias, and a range of solid tumors. It is only in HCL, with median response rates of about 90%, that it is clearly superior to conventional chemotherapy; however, there is considerable interest in including it as a part of multiparameter treatment with chemotherapy, radiotherapy, and surgery for other cancers.

TGFβ blocks the growth-promoting effects of cytokines such as EGF, PDGF, and the FGFs, and many malignant cells both produce and respond to it. A negative autocrine loop thus controls proliferation. In breast cancers, the cells often produce TGF but lose their ability to respond.[55]

IL-6 inhibits the growth of a variety of human cell lines derived from malignant tumors of breast, ovary, and myeloid cells, but it also has a dramatic effect in reducing tumor load in mice transplanted with several murine tumors, an effect that is largely lost if the animals are rendered immune deficient. Conversely, IL-6 is a potent growth factor for plasmacytoma and myeloma cells, and it has been shown that freshly isolated human myeloma cells from patients produced IL-6 in culture, indicating the possibility of an autocrine loop promoting growth in this cancer. Additional evidence also supports a paracrine role for IL-6, with production in myeloma arising not only from the myeloma cells but also from adherent stromal cells in the bone marrow. It is thus of great interest that monoclonal antibodies to IL-6 have shown an effect in retarding tumor growth in early trials.

Cytokines such as IL-6 and TNF also have an important role in regulating estrogen synthesis in peripheral tissue, including normal and malignant breast tissue. The activities of the aromatase, estradiol 17-hydroxysteroid dehydrogenase, and estrone sulfatase enzymes are all increased by IL-6 and TNF. Macrophages and lymphocytes, which invade many breast tumors, are thought to be an important source of factors such as cytokines that can modulate estrogen synthesis in malignant breast tissue.[426]

The incidence of breast cancer is reduced in immunosuppressed women.[426] Because cytokine production is also reduced in immunosuppressed women, this finding supports the concept that cytokines have an important role in breast cancer, possibly acting via stimulation of estrogen synthesis.[426]

Toxicity for Tumor Cells

The TNFs inhibit tumor cell growth by a direct cytotoxic effect, inhibit proliferation, and induce differentiation.[405] The mechanisms are arachidonic acid dependent and may involve the production of oxygen free radicals, which destroy the tumor cell DNA. These molecules have potent antitumor activities in murine models caused by direct inhibition of growth, immunomodulation, and effects on the vascular system. Unfortunately, extensive trials in human malignancies have been very disappointing, largely caused by dose-limiting toxicity when TNF is administered systemically, although isolated limb perfusion and intratumor injection appear promising. TNF can also stimulate growth of some malignant cells.

Modification of Host-Tumor Relationship, Local Spread, and Metastasis

In addition to the effects described previously, TNF also exhibits protumor effects. Transplanted ovarian carcinoma cells in nude mice possess an enhanced ability to invade peritoneal surfaces and metastases following transfection with

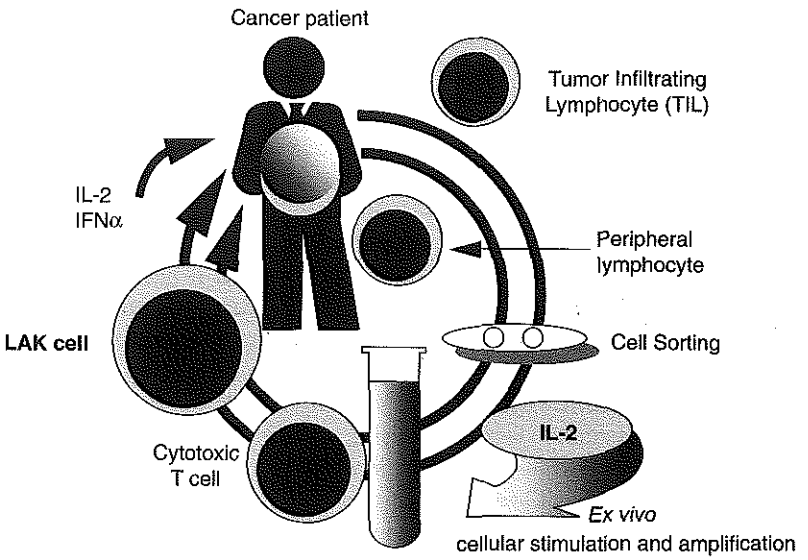

Figure 22-8 Generation of LAK cells in the laboratory.

the human TNFα gene. This suggests more subtle effects (e.g., on the production of adhesion molecules).

Because the control of metastasis is critical to the control of cancer progression, two chemokine receptors and their ligands stand out as likely targets for therapeutics: CCR7/CCL21 for lymph node metastases, and CXCR4/CXCL12 for lung, liver, bone marrow, and brain metastases.[601] It has been reported that the CXC chemokine receptor 4 (CXCR4) and its ligand CXCL12, also known as stromal cell–derived factor 1, or SDF-1, together govern the pattern of breast cancer metastasis.[375,601] In this study, it was suggested that metastatic cancer cells simply use signals that normally control leukocyte transport. Chemokines and their ligands represent one of the more important of these signals because they can be secreted by virtually all types of cells, but in different amounts and combinations. The synthesis of most requires inflammatory signals, whereas a few, such as CXCL12, are molecules of "resting" cells in virtually all organs. Specific combinations of chemokines, chemokine receptors or ligands, and adhesion molecules form a spatial and temporal code that determines which subgroups of human cells migrate and where they migrate.[378]

Immune Response to Tumor

The tumor-suppressor roles of cytokines include many regulatory effects on the immune system. The IFNs enhance the expression of MHC class I antigens on many different normal and malignant types of cells, making them susceptible to killing by cytotoxic T cells.

IL-2 stimulates peripheral blood lymphocytes, rendering a subpopulation of them more cytotoxic for tumor cells. This subpopulation of cells is known as lymphokine-activated killer cells (LAK cells) and probably form part of the NK cell population, which may be responsible for immune surveillance of potentially malignant cells. IL-2 is used therapeutically intravenously or subcutaneously, and in renal cell carcinoma and melanoma gives responses much better than chemotherapy. LAK cells may be stimulated ex vivo using lymphocytes derived from plasmapheresis and reinfused into the patient (Figure 22-8). For still greater specificity, tumor infiltrating lymphocytes (TILs) may be extracted and stimulated. Significant toxicity limits the dose of IL-2.

Tumor infiltrating lymphocytes are very important in immune competence against cancer. A study reported in 2003 demonstrated remarkable differences in the distributions of progression-free survival and overall survival according to the presence or absence of intratumoral T cells.[595] The 5-year overall survival rate was 38.0% among patients with epithelial ovarian cancer whose tumors contained T cells and 4.5% among patients whose tumors contained no T cells in islets. The presence of intratumoral T cells independently correlated with delayed recurrence or delayed death in multivariate analysis and was associated with increased expression of IFN-γ, IL-2, and lymphocyte-attracting chemokines within the tumor. The absence of intratumoral T cells was associated with increased levels of vascular endothelial growth factor.

IL-12 has been shown in animal studies to have potent antitumor and antimetastatic activity, probably by its actions stimulating Th1 cells and inducing IFNγ production.

Cytokines in most cases modulate tumor-specific inhibition dependent on direct lytic activity of cytotoxic CD8 T cells or on polarization of CD4 T cells. But tumor eradication also depends on noncytotoxic CD4 and CD8 lymphocytes releasing high amounts of proinflammatory cytokines that recruit distinct effector leukocytes at the tumor site. This series of events emphasizes the cytokine action in the tumor site upon several distinct cell types and immunoinflammatory mechanisms. However eradication of established tumors involves distinct mechanisms, each endowed with a different curative potential and not only cytokines.[108,486]

Mediation of Paraneoplastic Effects

Many hormonal, neurological, hematological, and other clinical and biochemical disturbances associated with malignant neoplasms (paraneoplastic effects) are considered to be mediated by cytokines. For example, the fever that so often accompanies cancer is mediated by IL-6, IL-1, and TNF and typically occurs in lymphoid malignancies in which these cytokines are released. Anemia may be mediated by TNF, thrombocytosis by IL-6, and cachexia by TNF and IFNγ. Bone reabsorption and hypercalcemia are induced by IL-1.

Cytokines and the Diagnosis of Tumors

A number of situations are emerging in which the measurement of cytokines may provide clinically useful information about prognosis and response to treatment of tumors. For example, great interest has surrounded the role of serum IL-6 measurements in assessing the prognosis in myeloma and in distinguishing it from monoclonal gammopathies of undetermined significance (MGUS). IL-6 levels are elevated in a higher proportion of patients with myeloma and correlate broadly with disease activity, proliferation index, and survival. Patients with MGUS generally have normal or low levels of IL-6, but unfortunately studies have not shown sufficient discrimination to be clinically useful in distinguishing these important conditions. In Hodgkin's disease and non-Hodgkin's lymphoma, there is a correlation between symptoms of fever and malaise (B symptoms) and IL-6 level; raised levels also predict a poorer prognosis. In studies of renal cancer, colorectal cancer, and melanoma, baseline C-reactive protein (CRP) or IL-6 levels have been shown to be related to response to treatment with IL-2, with responders having lower concentrations before therapy and a much greater increase during therapy. Elevated concentrations of the soluble IL-2 receptor (sIL-2R) have been found in a number of malignancies, in particular those of the lymphoid system and the leukemias. In children with acute lymphoid leukemia, raised levels predict relapse and correlate with survival. This is probably also true of adult HCL and T-cell leukemia, suggesting that the use of sIL-2R measurements could have a place in the management of the hematological malignancies. Of the solid tumors, lung cancer has attracted particular attention because raised levels may relate to survival and disease status following treatment, and tend to be higher in small cell lung cancer.

TNF expression or protein production has been demonstrated in many cancer cell lines and biopsies. For example, in ovarian and breast cancers, TNF mRNA or protein has been found in 50% to 70% of the tumors studied. Serum TNF and sTNFR levels are raised in a wide range of malignancies, and their measurement may be useful in follow-up studies.

A high proportion of patients with hematological malignancies have increased levels of the cytokine M-CSF that have been shown to relate to disease type, status, and response to therapy. In addition, elevated levels of this cytokine have been observed in ovarian cancer and have been found to correlate with disease status following treatment. In practice, there is great interest in the use of M-CSF together with CA125 as an index of therapy in this difficult cancer.

A number of the growth factors, such as the IGFs, PDGF, and the TGFs, show raised serum concentrations in various cancers. TGFα is of interest in that it is almost invariably raised in breast cancer irrespective of stage and was higher in the sera of patients with hepatocellular cancer than in normal subjects or those with hepatitis or cirrhosis. This growth factor is excreted in the urine, and urinary levels are often raised in head and neck cancer and may sometimes be useful for monitoring treatment.

INDIVIDUAL CYTOKINES

The structure, function, and clinical significance of many individual cytokines have been extensively studied. In this section, cytokines that are highlighted in Table 22-1 are individually discussed.

INTERLEUKIN-1

Interleukin-1 (IL-1) is a predominantly macrophage-produced interleukin, which mediates the host inflammatory response in innate immunity; two principal forms exist, designated α and β, with apparently identical biological activity. At low concentrations, IL-1 principally acts to mediate local inflammation, causing mononuclear phagocytes and endothelial cells to synthesize leukocyte activating chemokines. At high concentrations, IL-1 enters the blood stream and acts as an endocrine hormone, in some actions resembling TNF by its ability to cause fever, initiate hepatic synthesis of acute phase proteins, and induce cachexia.[138]

Synonyms

IL-1 has also been known as B cell–activating factor, catabolin, endogenous pyrogen, epidermal cell–derived thymocyte activating factor, fibroblast activating factor, hemopoietin-1, hepatocyte stimulating factor (HSF), leukocyte endogenous mediator, lymphocyte activating factor, mononuclear cell factor, osteoclast activating factor, proteolysis inducing factor, and serum amyloid A inducer.

General Characteristics

The IL-1 family has three members: IL-1α, IL-1β, and the IL-1 receptor antagonist (IL-1RA or IL-1γ), all three acting on the same receptors. The structures of the three molecules are related to a limited extent. There is a 20% sequence homology between the two forms of IL-1, which are encoded by two different genes; however, IL-1α and IL-1β are agonists, with IL-1RA being an antagonist having more similarities with IL-1β. The IL-1 family is also related structurally to FGF. Both forms (IL-1α and IL-1β) are stable tetrahedral globular proteins (bowl-like structure)[71] and are processed at the cell membrane or extracellularly to give the mature molecule.[152]

Most of the IL-1 activity in plasma is from IL-1β, IL-1α existing mainly in an intracellular or membrane-associated form.[1,152,437] IL-1 shares many of its functions with TNF, but important differences between IL-1 and TNF exist. For example, IL-1 is in general not toxic, and TNF is a potent cytotoxic effector (see the Biological Actions of TNF section). One of their shared functions is the induction of expression of the vascular cell adhesion molecule (VCAM) by endothelial cells. Studies have indicated that TNF may be more important than IL-1 in induction of VCAM expression at least in the nasal mucosa.[568]

Other general characteristics of IL-1 include:

Molecular Weight

Literature values for the molecular weights of IL-1, IL-1α, and IL-1β vary from 17 to 17.5 kDa.* The molecular weight of the IL-1 receptor core has been reported to be 17 kDa, with three distinct glycosylated forms (18, 22, and 22 kDa).[389]

Cross-Reactivity

The cross-reactivities (amino acid sequence homology between human and mouse) for IL-1 and its receptor include IL-1α (62%), IL-1β (68%), and IL-1RA (77%).[71]

Chromosomal Location

The chromosomal locations of IL-1 and its receptors are 2q12-21 (IL-1α), 2q13-21 (IL-1β), 2q12 (IL-1R type I), and 2q12-22 (IL-1R type II).

Cellular Origin

Activated mononuclear phagocytes are the major cellular sources of IL-1, but almost all nucleated cells are capable of secreting IL-1α and IL-1β after stimulation (Figure 22-9). Also, important sources of IL-1 are classical antigen-presenting cells, including monocytes and macrophages, Langerhans' cells, dendritic cells, B lymphocytes, endothelial cells, T cells, NK cells, astrocytes, keratinocytes, and fibroblasts.[71,152]

Control of Synthesis and Release

Mature forms of IL-1 depend on proteolytic cleavage of precursor forms (prointerleukin-1) into the cytoplasm. Mature molecules and IL-1α precursor are biologically active, but IL-1β precursor is inactive. Activation of this latent form is produced by proteases (such as serine proteases), appropriate proteases from monocytes and/or macrophages, chymase in mast cells, and an aspartate-specific protease called IL-1 converting enzyme (ICE).[341] Normally IL-1 synthesis and secretion occur after cellular stimulation (Box 22-3), but IL-1α is present constitutively in large amounts as a preformed biological response modifier in epithelial cells, such as keratinocytes in the skin, sweat, urine, and amniotic fluid. Damage or stimulation of these cells results in the liberation of enormous amounts of active IL-1.[472] Prointerleukin-1β (pro-IL-1β) is the only known physiological substrate of the ICE. The structural similarities of ICE with a nematode gene, *ced*-3, which initiates a cell death program, suggest that IL-1 could be released from macrophages during apoptosis.[341] Pro-IL-1β has been demonstrated to be a substrate of ICE that is relevant to cell death, and depending on the temporal cellular commitment to apoptosis, mature IL-1β may function as a positive or negative mediator of cell death.[174] However, IL-1β also suppresses apoptosis in CD34 positive bone marrow cells through activation of the IL-1 receptor type I and the subsequent production of endogenous GM-CSF.[444] Following lipopolysaccharide (LPS) stimulation of monocytes, intracellular activity of IL-1 is detected in 30 minutes, extracellular IL-1 activity is detected in 60 minutes, and high levels occur in 3 hours.[152] Urate or silicate

*References 1, 71, 152, 341, 389, 421, 436.

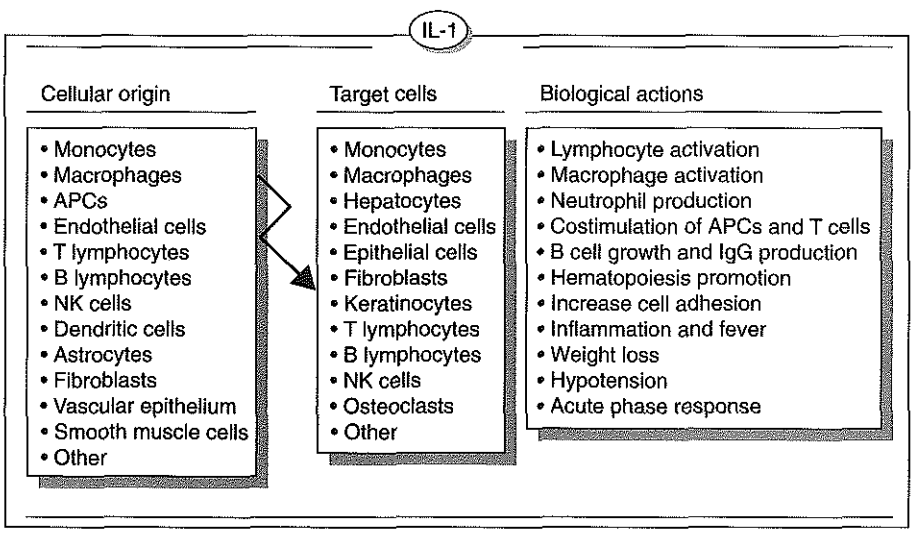

Figure 22-9 Cellular origin, principal target cells, and biological actions of IL-1.

particles and adjuvants, such as aluminum hydroxide, are other external stimuli for cells to produce IL-1. Concerning the regulation of ICE, a cowpox virus inhibitor known as cytokine response modifier A (CRMA) has been described that inhibits the host inflammatory response through the inhibition of ICE.[71] IL-1RA is synthesized by the same cells that secrete IL-1, and an intracellular form has been identified.[71]

Prostaglandins, a class of lipid-derived inflammatory mediators, can also regulate IL-1 expression; for example, IL-1 production by macrophages is enhanced by leukotrienes, but is suppressed by products of the cyclooxygenase pathway, such as prostaglandin (PG) E2 (PGE2). Increased circulating levels of IL-1 are also observed during the luteal phase of the menstrual cycle[268,297,550,556] and during strenuous exercise.

Proteases that activate the precursor forms of IL-1 belong to a class of highly specific cellular proteases termed *caspases*. The number of enzymes in this family of proteases keeps growing, with new members continually being identified and a unified nomenclature being proposed. All caspases share two key features: They require an aspartic acid at the cleavage site, and they are all synthesized as proenzymes that are activated by cleavage at aspartate residues at sites resembling their own targets. This raises the possibility of autoprocessing and transactivation among caspases. This has been shown to be the case for activation of caspase-1 (ICE) by caspase-4, caspase-3 by caspase-1, and caspase-3 and caspase-7 by caspase-10.[347]

IL-4 and IL-10 are inhibitors of IL-1 synthesis, as are glucocorticoids that are produced in response to IL-1, and may represent a feedback mechanism of IL-1 secretion.[437] Multiple stimuli are likely to operate in vivo to promote IL-1β posttranslational processing, such as anion transport inhibitors.[418]

Genetic deletion of IL-1 receptors results in the overproduction of IL-1 mRNA in organs known to produce cytokines during pancreatitis, even when the severity of pancreatitis is lessened. This suggests that a negative feedback loop exists between the IL-1 receptor and IL-1 gene expression.[394]

Receptors (IL-1R)

There are two types of IL-1 receptors (Figure 22-10): type I (CDw121a, 80 kDa) and type II (Cw121b, 60 kDa). They are transmembrane glycoproteins and members of the Ig superfamily that bind IL-1α, IL-1β, and IL-1RA. They are profusely distributed on a variety of cell types,[71,152,341] but only type I receptor (IL-1RI) provides intracellular signal. Type II receptor (IL-1RII) acts as an IL-1 regulator (antagonist or decoy receptor). IL-1RI is expressed mainly by T cells, B cells, eosinophils, fibroblasts, endothelial cells, some cells of the nervous system, and muscle cells (25 to 1000 receptors per cell) and IL-1RII by B lymphocytes, activated T lymphocytes, monocytes, neutrophils, eosinophils, placental cells, endothelial cells, fibroblasts, some cells of the nervous system, and megakaryocytes (200 to 8000 receptors per cell).[152,437]

The type I receptor has a large cytoplasmic domain and transmits signals when it binds IL-1; the signaling pathway is not fully known, but shares some components with those

- Urate crystals
- *Phorbol myristate acetate* (PMA)
- UVB radiation (on keratinocytes)

*EBV induces a rapid accumulation of IL-1 and IL-1RA mRNA in neutrophils that was associated with the later appearance of considerable amounts of IL-1α, IL-1β, and IL-RA proteins. The elevated levels of IL-1RA detected for EBV-stimulated neutrophils might be part of a mechanism used by the virus to evade the immune system.

†The cytokine cascade IL-1, TNF, and IL-6 is responsible for many cellular events that are present in acute inflammation, and almost all the inflammatory mediators are enhancers of IL-1 secretion. Also IFNγ and GM-CSF prime cells for IL-1 release after exposure to inducers.

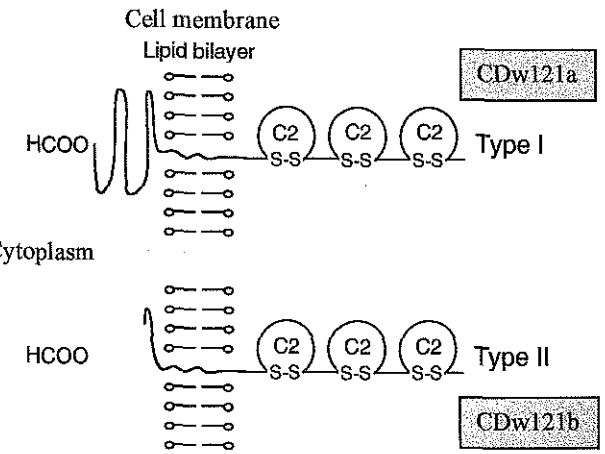

Figure 22-10 Illustrations of the type I and II receptors of IL-1.

used by the IL-18 and TLR families. Binding to as few as five copies of IL-1RI on a cell can be sufficient to produce a response.

A fibroblast may carry several thousand IL-1 receptors; resting T cells express as few as 50, but this number increases after activation. Binding leads to endocytosis of IL-1 together with its receptor.

The biological activity of IL-1 is regulated by IL-1 itself (it enhances synthesis and secretion of IL-1 but suppresses expression of IL-1 receptors); IL-1RII; PGE2, which suppresses IL-1 production and IL-1RA; and TGFβ, which abrogates the immunoinflammatory effects of IL-1. However, the principal functional inhibitor of IL-1 is IL-1RA, acting as a competing molecule for IL-1 receptors. The production of this antagonist is increased by GM-CSF, IL-4, IL-10, and TGFβ. A 1996 study found that IL-1RA is also a common regulatory product of inflammatory macrophages (involved in types 1 and 2 granulomas) and is particularly promoted by CD4 Th1 cytokines, IFNγ, and TNFα.[449] A soluble receptor found in normal human serum has also been described that binds preferentially to IL-1β.[71]

The type II receptor has a small cytoplasmic domain and cannot transduce signals. The extracellular domain of IL-1RII is released in soluble form at sites of local inflammation and into the serum during times of systemic inflammation. This soluble IL-1RII is produced in relatively large amounts, binds IL-1β much more strongly than it binds IL-1α or IL-1RA, and functions as an endogenous inhibitor of IL-1β. Both soluble and cell-associated forms of IL-1RII have therefore been called IL-1 decoy receptors.

Signal Transduction

IL-1 induces hydrolysis of phosphatidylethanolamine (but not other phospholipids), which will release diacylglycerol (DAG) and activate protein kinase C (PKC) without releasing calcium. It has also been reported to activate a G-protein–regulated adenyl cyclase.[71] Association of IL-1 with Janus protein tyrosine kinase signal transducers and activators of transcription (JAK-STAT) signaling has remained unresolved. Tsukada and co-workers have reported an element termed LPS and IL-1–responsive element in the human prointerleukin-1β gene that can be immediately induced by either LPS or IL-1 protein to bind a tyrosine-phosphorylated protein.[539] This LPS and IL-1–induced factor (LIL-factor) is recognized by an antibody raised against the N terminus of STAT1 but not by those specific for either the C terminus of STAT1 or any other gamma interferon activation (GAS)–binding STAT. Moreover, the unique DNA-binding specificity and antigenicity of this factor suggest that LPS, IL-1, and IL-6 may use a common signaling pathway.

Biological Actions

IL-1 plays a central and primary role in the inflammatory response and tissue repair, and weak evidence supports an action of IL-1 as a physiologically important co-stimulator of mature T lymphocyte activation.[1] In a review,[129] Dinarello reports that investigators have studied how production of the different members of the IL-1 family is controlled, the various biological activities of IL-1, the distinct and various functions of the IL-1R family, and the complexity of intracellular signaling. Special attention is paid to IL-1β converting enzyme and programmed cell death (apoptosis). The role of IL-1 in hematopoiesis, leukemia, atherosclerosis, and growth of solid tumors is also discussed.

Systemically, IL-1 exerts a biological effect at the level of a single cell and also has indirect effects (Table 22-4). Its biological activities depend on the quantity of cytokine released.[1] At low concentration, it acts as a mediator of the local immunoinflammatory reaction, inducing a cascade of secondary cytokines in a large number of types of cells (macrophages, endothelial cells, fibroblasts, synovial cells, and keratinocytes), enhancing leukocyte and/or endothelial cell adhesion, and inducing CD4 T-cell proliferation and B-cell growth and differentiation. The latter demonstrates its potential for functional autocrine pathway activation mediated by IL-1α and suggests that the level of expression of IL-1RI may function as a significant control point in physiological IL-1 mediated autocrine pathways.[202] At high concentration, IL-1 diffuses into the blood and subsequently exerts an endocrine action on the brain, liver, adrenals, and other organs; it acts as an endogenous pyrogen, inducing fever, stimulating the synthesis of acute phase proteins, and inducing cachexia. The exact (paracrine) endocrine role of IL-1 on the peripheral immune system, namely on T cells, is not well characterized, but it is known to affect the cell cycle. It regulates IL-2 production (increasing the density and affinity of IL-2 receptors and increasing the production of IL-2). Generally, it seems that every cell, immunoinflammatory or not, is affected by IL-1.[152] The main importance for immunity, however, seems to lie in its ability to enhance the activation of T helper lymphocytes by APCs. IL-1 acts in an autocrine manner to induce or increase expression of various adhesion molecules, IFNγ receptors, and class II MHC proteins on the APC surface and so increase the efficiency with which the APC can bind and activate Th cells.

Dendritic cells are highly effective APCs capable of stimulating the differentiation of naive lymphocytes into effector cells. Specific properties of the dendritic cells determine the quality of immune responses that they initiate. IL-1 and IL-1Ra play a biologically relevant role in the positive and negative regulation of dendritic cell activation. In conjunction with CD40L, IL-1 sends a powerful activation signal to dendritic cells that could be distinguished from other modes of activation. This signal enables the production of proinflammatory cytokines by dendritic cells, and enhances the differentiation of naive T cells into effectors of type 1 cellular immune responses.[573]

IL-1 plays an important role in the pathophysiological responses to infection and inflammation, in part by mediating its own production and that of other proinflammatory cytokines. However, the relative contribution of IL-1α and

TABLE 22-4 Biological Activity of IL-1

Target	Biological Activity
Single Cell Level	
Thymocytes	Proliferation
T lymphocytes	Production of IL-2 and IFN; induction of IL-2 receptors; proliferation, adhesion, inhibition of IL-4 synthesis
Pre-B lymphocytes	Differentiation and expression of IgM
B lymphocytes	Proliferation and antibody production
NK cells	Activation of cytotoxicity
Macrophages	Secretion of IL-1 and prostaglandin (PGE2), chemotaxis, cytotoxicity
PMN neutrophils	Enzyme release; oxidative burst; chemotaxis; production of collagenase
Endothelial cells	Proliferation; synthesis of TNF and IL-6; angiogenesis; prostaglandin synthesis; procoagulant activity; VCAM and E-selectin expression
Epithelial cells	Proliferation; production of collagen, type IV
Keratinocytes	Proliferation; secretion of TNF, IL-6, and GM-CSF
Fibroblasts	Proliferation; secretion of IL-6, collagen, collagenase, and PGE2
Osteoclasts	Bone resorption and calcium release; collagenase synthesis
Chondrocytes	Cartilage breakdown and proteoglycan release; plasminogen activator; prostaglandin and collagenase synthesis
Synovial cells	Proliferation; prostaglandin and collagenase synthesis
Muscle cells	Amino acid oxidation and proteolysis; prostaglandin synthesis
Hepatocytes	Increase in acute phase protein synthesis
Systemic Effects	
Brain	Prostaglandin synthesis; fever; somnolence; anorexia
Adrenals	Induction of ACTH and glucocorticoid production
Blood	Granulocytosis
Bone marrow	Stimulation of hematopoiesis; release of neutrophils into the blood; potentiation of CSFs
Pancreas	Insulin secretion
Body (in general)	Cachexia
Indirect Effects	From cytokine cascades, especially from TNFα and IL-6, through synergy with other cytokines, such as GM-CSF*

From references 1, 90, 152, 349, 457, 528, 568.

*Antigen-presenting cells (APC) can up regulate GM-CSF production through IL-1b and through CD28 triggering by B7 molecules. As GM-CSF itself up regulates B7 expression and IL-1β production by APC, a bidirectional regulatory feedback pathway between APC and T cells seems to modulate GM-CSF production.[229]

IL-1β to the inflammatory response has not been elucidated. This suggests that either IL-1β is not essential for the in vivo systemic response to LPS or that its role can be fulfilled by other cytokines with overlapping activities.[158]

Clinical Significance

IL-1 has been implicated in the pathogenesis of (1) rheumatoid arthritis (RA), (2) septic shock, (3) periodontitis, (4) malignancy, (5) asbestosis, (6) tuberculosis, and (7) human immunodeficiency virus (HIV) infection. Its presence has also been correlated with disease activity or differential diagnosis (synovial fluids, gingival fluids, or even serum). For example, patients with nonallergic bronchial asthma were characterized by increased levels of IL-1β and IL-6 produced by monocytes.[274,368]

IL-1 gene expression is selectively induced in tissue involved in multisystem organ failure during acute pancreatitis, suggesting a role in the pathogenesis of distant organ dysfunction.[394] Acute eosinophilic pneumonia is characterized by locally high levels of IL-5, IL-1RA, and soluble type II IL-1 receptor in the alveolar space.[6] IL-1 has also been found to be associated with inflammatory intestinal diseases, which induce intestinal epithelial cells to produce several cytokines and acute phase proteins (APP) during an inflammatory response. Little is known about the type of IL-1R expressed by intestinal epithelial cells and the effect of cytokines on the expression of these receptors. However, down regulating the expression of the type I IL-1R was suggested as a possible mechanism to limit the effect of IL-1 on intestinal epithelial cell function during the mucosal

inflammatory response.[354] Systemic inflammation induces an enhancement of melanoma cell metastasis and growth by IL-1–dependent mechanisms in vivo. In vitro, the mechanism(s) is consistent with IL-1–mediated increase in expression of mannose receptors and production of tumor cell growth factor(s) from the endothelium.[555] Tuberculosis is characterized by a cellular immune response mediated by various cytokines, including IL-1β released by stimulated mononuclear cells. It has been established that IL-1β plays an important role in local and systemic inflammatory response in tuberculosis.[360] In patients with diffuse panbronchiolitis, the relative amounts of IL-1β and IL-1RA or IL-8 may contribute to the neutrophil-mediated chronic airway inflammation.[249] HIV-infected individuals have experienced episodes of localized or systemic bacterial infections caused by gram-negative bacteria associated with the production of proinflammatory cytokines. For example, antiinflammatory cytokines inhibit LPS plus GM-CSF–stimulated HIV expression, and this effect closely correlates with inhibition of IL-1β release and, in particular, with up regulation of endogenous IL-1RA production. Thus the balance between an endogenously produced viral inducer (IL-1β) and an inhibitor (IL-1RA) may represent an important pathway leading to modulation of HIV expression from monocytic cells.[193]

Therapeutic Applications

IL-1 may be useful in protecting patients against lethal doses of radiation and in the stimulation of hematopoiesis. However, the therapeutic application of IL-1 that had generated the greatest interest is the development of anti-IL-1 therapies using either IL-1RA, soluble IL-1R, or other antagonists capable of an antiinflammatory and immunosuppressive effect. Although not very effective, IL-1 has been used in RA and septic shock.[88] Curiously, short-term use of inhibitors of cyclooxygenase (that blunts PGE2-mediated symptoms, such as fever and pain), such as aspirin or ibuprofen, does not decrease IL-1 but results in a "rebound" increase in cytokine-induced cytokine synthesis (IL-1, IL-2, IL-6, TNF, and GM-CSF).[155] Also, anion transport inhibitors—such as tenidap—that suppress cytokine processing independently of the initiating stimulus are attractive candidates as therapeutic regulators of IL-1 production.[418] IL-1 also plays a strategic role in the growth of cancer cells in inflammatory tissue; because IL-1RA is without side effects in humans, studies on intraoperative infusion of IL-1RA during tumor resection may be indicated.[555] The use of IL-1 in humans is associated with dose-limiting toxicity that resembles that of TNFα or IL-2. Activation of neutrophils is thought to contribute to the toxicity caused by these two cytokines but, unlike TNF, IL-1 does not cause neutrophil degranulation in humans, despite its ability to cause neutrophilia and the rapid release of IL-6, IL-8, and nitrite and/or nitrate.[395]

INTERLEUKIN-2

Interleukin-2 (IL-2) is an interleukin produced by T cells in response to antigenic or mitogenic stimulation, acting to regulate the immune response. It (1) stimulates the proliferation of T cells and the synthesis of other T-cell–derived cytokines, (2) stimulates the growth and cytolytic function of NK cells to produce LAK cells, (3) is a growth factor for and stimulates antibody synthesis in B cells, and (4) may promote apoptosis in antigen-activated T cells. IL-2 is used as an anticancer drug in the treatment of a wide variety of solid malignant tumors.[138]

Synonym

IL-2 has also been known as T-cell growth factor (TCGF).

General Characteristics

IL-2 is a globular protein composed of six α-helical regions (A, B, C, D, E, and F) with a disulfide bridge.[71] IL-2 contains variable amounts of carbohydrate in its molecular structure. However, the carbohydrate does not appear to affect the biological function of IL-2.[472] The polypeptide structure of IL-2 consists of 133 amino acid residues with one intramolecular disulfide bridge between residues 58 and 105.[152] Native IL-2 is folded into a globular protein containing two sets of paired parallel α-helices, each sheet oriented at a slight angle to the other. This α-helical folding motif is common to several cytokines, including IL-3, IL-4, IL-5, IL-6, IL-7, GM-CSF, and G-CSF with the WSXWS (tryptophan-serine-X-tryptophan-serine, where X stands for a variable amino acid residue) motif in the amino acid sequence of their receptors.[1]

This cytokine was discovered in the supernatants of T-cell cultures that had been stimulated by antigens or mitogens, such as phytohemagglutinin (PHA). The recognition of IL-2 as a growth and proliferation factor for lymphocytes (namely T cells) made it possible to grow and expand infected T cells for extended periods of time. This allowed the characterization of human T-lymphotropic virus type 1 (HTLV-1) and HIV.[485]

IL-2 represents the most important signal for clonal expansion of T cells. This is achieved by the binding of IL-2 to the high-affinity receptors expressed only by the activated T lymphocytes producing IL-2 (autocrine action) or by nearby activated T or B lymphocytes (paracrine action). Resting T and B cells are limited to the expression of the intermediate affinity receptor. IL-2 does not circulate in the blood at high levels during physiological immune responses and consequently does not act as an endocrine growth factor.[1,152]

Other general characteristics of IL-2 follow:

Molecular Weight

Depending on the degree of glycosylation, literature values for the molecular weight of IL-2 vary from 14 to 23 kDa.[1,71,152,389,472]

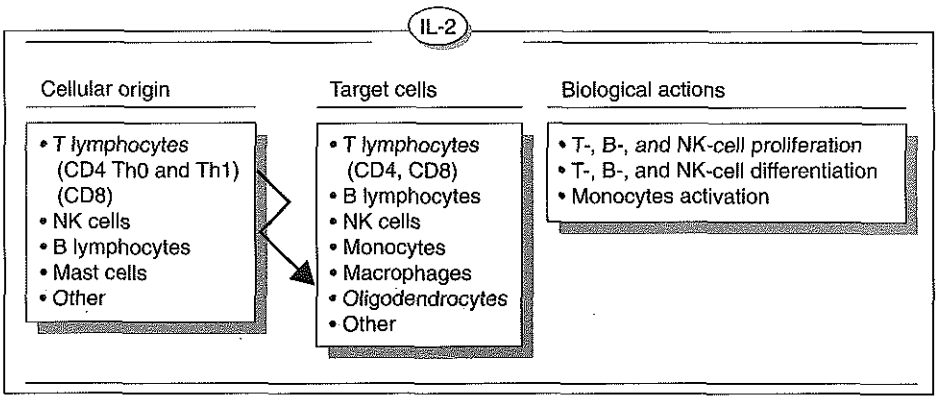

Figure 22-11 Cellular origin, principal target cells, and biological actions of IL-2.

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-2 is 60%.[71] Human IL-2 is active on mouse lymphocytes, but mouse IL-2 is not active on human lymphocytes.

Chromosomal Location

The chromosomal locations of IL-2 and its receptor are 4q26-27 (IL-2), 10p15-14 (IL-2R α-chain), 22q11.2-12 (IL-2R β-chain), and Xq13 (IL-2R γ-chain).

Cellular Origin

Activated T cells, namely CD4 T cells (Th0 and Th1), and in lesser quantities CD8 lymphocytes and NK cells, all synthesize IL-2 (Figure 22-11). B lymphocytes and mast cells can also produce IL-2.[441,472]

Control of Synthesis and Release

The principal inducers of IL-2 synthesis in vivo are the activators of T lymphocytes. In vitro they include mitogens, phorbol esters, calcium ionophores, and antibodies to cell surface receptors (e.g., CD2, CD3, and CD28).

IL-2 does not exist as a preformed cytokine but is rapidly and transiently synthesized after stimulation, with an early peak of secretion occurring about 4 hours after cellular activation.[1,472] The regulation of IL-2 release is mainly dependent on IL-2 gene expression, which is under inducible control by *cis*-acting regulatory sequences within the IL-2 enhancer. Binding sites have been identified in this region for a nuclear factor of activated T cells (NFAT), NF-κB, AP-1, and octamer proteins. As in other cytokines, a posttranslational control also operates to control the stability of mRNA in the 3′ untranslated region of the IL-2 genetic message.[341] Furthermore, the interaction between APC and lymphocytes is an important regulatory mechanism for IL-2 production and biological activity. Two signals from the APC (interaction of antigen with its specific T-cell receptor [TCR]-CD3 complex and secretion of IL-1) induce both the expression of the gene encoding IL-2 by responding cells and the expression of IL-2 receptors (IL-2R).[152,472] The proliferation rate of activated T cells (one of the principal cellular sources of IL-2) becomes concentration dependent when maximal IL-2R expression occurs. The presence of antigen or mitogen is required for continuous IL-2R expression. Consequently, once antigen or mitogen disappears, IL-2R density declines and cell proliferation drops, followed by a decrease in IL-2 synthesis.[152] It has been demonstrated that individually, IL-2 and TGFβ1 have contrasting effects. For example, TGFβ1 alone down regulates events that are associated with IL-2–mediated signal. When present together, IL-2 and TGFβ1 up regulate activation signals and proliferation of rapidly dividing CD4 T cells.[21] PGE2 inhibits the acquisition of the ability to produce IL-2 and IFNγ by acting directly on naive T cells.[262]

Receptor (IL-2R)

The IL-2 receptors are composed of three noncovalently linked polypeptide chains: α, β, and γ. These chains (or their complex) form the basis for three kinds of IL-2 receptors:

Low-Affinity Receptor

The α-chain (IL-2Rα, CD25), originally called Tac (T activation), is a 55-kDa polypeptide (also named p55) that is a low-affinity receptor ($K_d \cong 10^{-8}$ M). Cells that only express this receptor show detectable biological response to IL-2.[1,152] IL-2Rα is not found on resting T cells, but it is efficiently induced by T-cell activation.[152] A site on the IL-2B α-helix is thought to bind to the p55 receptor.[71]

Intermediate-Affinity Receptor

The β-chain (a polypeptide with 70 to 75 kDa, called p70 or p75, CD122) is a member of the receptor family characterized by the WSXWS motif and is expressed coordinately with the γ-chain (a 64-kDa polypeptide, also a member of the WSXWS family) forming a complex designated IL-2Rαβγ. This is the intermediate-affinity receptor ($K_d \sim 10^{-9}$ M) for IL-2, expressed constitutively by resting T lymphocytes (also by CD8 T cytotoxic cells). It is not expressed by CD4 Th

cells,[152] NK cells, macrophages, neutrophils, and other cells causing growth. The β-chain alone binds IL-2 with low affinity, and the γ-chain does not bind IL-2, common γ-chain (p64) together with IL-4R, IL-7R, IL-9R, IL-13R, and IL-15R binds IL-2. Both the β- and γ-chains are required for ligand internalization and signal transduction but not the α-chain.[152] Heterodimers α/γ or α/β form receptors of intermediate affinity.

High-Affinity Receptor

The αβγ-association (IL-2Rαβγ) produces the high-affinity receptor ($K_d \sim 10^{-11}$ M) that is expressed only by activated T (about 2000 binding sites per cell) and B lymphocytes, the latter after stimulation by IL-4 and Ig-receptor binding.[152,341] Also, the control of IL-2 and IL-2Rα-chain production is closely and contemporaneously related, contrasting with the simplicity of β- and γ-chain expression. This is very important because the physiology of cytokines relies on interactions with constitutive and induced receptors.

Although the α-chain is very important (and fundamental for the appearance of high-affinity IL-2R), the γ-chain has a key role based on its molecular pluripresence (found in IL-4, IL-7, IL-9, and IL-15 receptors but possibly not the IL-13 receptor), constitutive expression by lymphoid cells, and genetic defect in the immune response. The latter results in X-linked severe combined immunodeficiency (XSCID) characterized by profoundly diminished cell-mediated and humoral immunity.[152,237,313,341]

As a general rule, resting cells express low- or intermediate-affinity receptors, thereby requiring high levels of IL-2 to have a biological response (as previously stated, the low-affinity receptor is not yet associated with any biological known response to IL-2). On an appropriate stimulus (e.g., antigen-mediated T-cell activation or the IL-2 itself), IL-2Rα is rapidly expressed, thereby reducing the concentration of IL-2 required for cellular growth and proliferation. Nevertheless, IL-2 can also regulate the expression of high-affinity receptors (e.g., IL-2-receptor interactions cause the density of IL-2Rαβγ to diminish).[152] Both IL-2 binding and cellular stimulation can be blocked by antibodies against either α- or β-chains.[1]

Signal Transduction

At least two distinct cytoplasmic regions of the IL-2Rβ-chain are involved in IL-2–mediated cellular signaling: a serine-rich region for induction of *c-myc* and cell proliferation and an acidic region for physical association with *src*-like protein tyrosine kinase (PTK) $p56^{lck}$, activation of $p21^{ras}$, and induction of c-*fos* and c-*jun*.[71]

Many cytokines and growth factors use the JAK-STAT pathway to generate a signal from the cell membrane to the nucleus. While homodimerizing cytokine receptors may transmit a signal via a single form of JAK (i.e., growth hormone receptors), several multicomponent cytokine receptors have been shown to require simultaneous activation of pairs of different JAK kinases (i.e., IFN receptors).[277] In this study, the authors verified the ability of IL-2 to cause tyrosine phosphorylation and activation of JAK1 and JAK3 and demonstrated that IL-2 stimulated JAK3 to a significantly larger extent than JAK1 in human T lymphocytes. Moreover, STAT5 was found to be the dominant STAT transcription factor used by IL-2 in human T cells and specifically required a COOH-terminal region of IL-2Rβ (Ser386-Val525), and STAT5 recruitment was not correlated with activation of IL-2Rγ or JAK3. Several signaling pathways regulate the IL-2 gene, including the NFkB pathway.

Soluble Receptor (sIL-2R)

The measurement of soluble cytokine receptors is generally considered of great importance in the characterization of the immunoinflammatory response. Chronic T-cell stimulation leads to shedding of IL-2Rα. The soluble receptor chains may bind free IL-2, blocking its action on cellular receptors. However, the greater affinity of IL-2Rαβγ compared with shed receptor alone suggests that they do not contribute significantly to immunosuppression. Clinically an increased level of soluble IL-2Rα in a biological fluid, such as serum, is associated with a potent immune response that is often dependent on a strong antigenic stimulation.[1]

Biological Actions

Originally known as a T-cell growth factor, IL-2 is now clearly connected with a variety of cellular actions on T and B lymphocytes, NK cells (Box 22-4), macrophages, monocytes, oligodendrocytes, and fibroblasts.

T Lymphocytes

IL-2 supports growth and proliferation (from the G1 to S phase of the cell cycle) of antigen- or mitogen-primed T lymphocytes and is an important determinant of the magnitude of T-cell–dependent immune responses (IL-2 is the most potent T-cell growth factor and is very important in determining the T-cell functionality).[263] Failure to produce adequate amounts of IL-2 has been described as a cause of antigen-specific T-cell anergy (decreased immunity or lack of immunity to an antigen). However, mice with IL-2 gene knockout appear to have relatively normal immune responses, suggesting that many IL-2 activities may be redundant.[1] This is particularly demonstrable in that other cytokines (e.g., IL-4, IL-6, IL-7, IL-9, and IL-15) can induce similar effects on T and B lymphocytes.[472] The magnitude and duration of the immune response are determined by the interaction of IL-2 with high-affinity IL-2R,[152] which seems to be a good argument for the value of IL-2 in immune responses. Moreover, the kinetic and equilibrium differences between the mouse and human receptor complexes and between IL-2 and IL-15 binding to these receptors clarify the roles of the α- and γ-subunits in the differential response of cells to different cytokines that may be present simultaneously in the environment.[25]

High-dose IL-2 and IL-15 enhance the in vitro priming of naive CD4 T cells for IFNγ but have differential effects on

BOX 22-4 Summary of IL-2 Effects on Lymphocytes*

T Cells
- Growth and proliferation
- Function
- Magnitude and duration of immune response
- Enhanced mobility
- Secretion of IFNγ, TNFα, and TNFβ

CD4 T Cells
- Interaction with B cells, leading to enhanced antibody production
- Interaction with class II MHC molecules on macrophages, leading to IL-1 secretion

CD8 T Cells
- Activation of T cells cytotoxic for tumor cells
- Secretion of IFNγ, leading to macrophage activation and enhanced IL-1 production

B Cells
- Growth and proliferation
- Antibody synthesis
- Immunoglobulin isotype switching IgE production of anergic Th2 cells
- Induces LAK cell capacity
- Modulates human leukocyte antigen expression
- Induces secretion of cytokines

NK Cells
- Proliferation
- Increase cytotoxicity by NK
- Enhanced NK activity
- Induction of LAK activity
- Secretion of TNFα and IFNγ

*References 1, 25, 152, 161, 263, 423, 441, 472.

priming for IL-4.[469] Uncommitted human CD4 CD45RA CD45R0neg* CD25neg CD71neg human leukocyte antigen (HLA)-DRneg T cells can be primed for a Th2 phenotype (see earlier section on inflammation) before they encounter TCR signals and before they are exposed to IL-4. As such, a significant fraction of uncommitted T cells may be primed in vivo for a Th2 phenotype independent of antigen (Ag) and IL-4 if they are exposed to Th1 cell-derived IL-2 and simultaneously interact with accessory cells bearing the natural CD28 ligands B7-1 and B7-2. When stimulated by a specific Ag, such primed Th2 precursor cells may provide a source of IL-4 to promote Th2 immunity.[62] IL-2 and IL-7 reciprocally induce IL-7 and IL-2 receptors on γδ T-cell receptor-positive intraepithelial lymphocytes. The sources of these two cytokines for γδ-T cells were neighboring epithelial cells (IL-7) and αβ-T cells (IL-2 and IL-7).[177]

Paradoxically, however, this cytokine appears equally important in limiting T cell responses and eliminating autoreactive T cells. Prolonged or repeated activation in the presence of IL-2 causes T-cell apoptosis and mutations that inactive IL-2 or its receptor lead to excessive T-cell proliferation and autoimmunity.[114] IL-2 is thus a two-edged sword that initiates immune responses but also limits their intensity and duration.

B Lymphocytes

IL-2 stimulates growth and proliferation of B lymphocytes, leading to antibody synthesis. It does not appear to cause Ig isotype switching.[1] It has been demonstrated that IL-2 restored the helper function of anergic Th2 cells for IgE production by B cells; this effect was greatly enhanced by the addition of IL-4 or IL-13.[161] Also, IL-5 synergizes with Th1 cells to induce B-cell responses to IL-2, which are maintained following T-cell removal.[423] IL-2 induces LAK cell capacity, modulates HLA expression, and induces secretion of other cytokines from different activated cells, like T and B lymphocytes, NK cells, and mononuclear phagocytic cells. This is of particular importance because some cytokines (such as IFNγ) augment NK cell activity, induce the generation of T cytotoxic (Tc) cells, activate macrophages, and modulate the expression of class II MHC molecules.

Other Cells

IL-2 often synergizes with other cytokines (notably IL-12) to induce IFNγ production by NK cells and to increase cytotoxicity by NK and LAK cells.[152] The expression of the receptor for this cytokine on NK cells is, however, continuous in character, but only a very small percentage of these cells have receptors of great affinity.[441] The study of differential use of Janus kinase-signal transducer activator of transcription signaling pathways in the stimulation of human NK cells by IL-2, IL-12, and IFNα has demonstrated a differential phosphorylation and consequent differential activation of both separate and overlapping STAT proteins by IL-2, IL-12, and IFNα. This may provide a molecular basis for the similarities and differences in the actions of these cytokines on NK cells.[591]

The biological actions of IL-2 on other types of cells are less well known, but IL-2 receptor chains have been detected on mononuclear phagocytes. Although they have been known to respond by cytokine synthesis and increase of cell-killing activities, a more specific IL-2 action in this cell population has not been established.[1,472] Mast cells and Langerhans' cells also express IL-2 receptors following activation. Whether IL-2 induces proliferation or alters the activities of these cells is as yet unclear.[472] Investigations reported in 1996 support the concept that a self-directed cytotoxicity against pulmonary fibroblasts is generated during lymphocyte activation with recombinant IL-2.[592]

*CD45R0neg means no expression of CD45R0 (negative). All positive CDs are presented without the plus (+) sign.

Clinical Significance

Excessive production of IL-2 has been reported in pregnancy, multiple sclerosis, sarcoidosis, multiple myeloma, acute rheumatic fever, and chronic rheumatic heart disease.[385,472]

Production of IL-2 is diminished in (1) advanced age, (2) diabetes, (3) RA, and (4) Sjögren's syndrome.[472] Also, reduced synthesis of IL-2 is associated with both acquired immunodeficiency syndrome (AIDS) and SCID.[472] However, 1995 findings support the hypothesis that lymphocytic alveolitis in asymptomatic HIV-positive patients results from IL-2–dependent in situ proliferation of CD8 cytotoxic T cells.[492] Failure to produce either IL-2 or IL-2R is associated with the absence of a T-cell–mediated immune response.[152] Patients with chronic mucocutaneous candidiasis present altered antigen-stimulated IL-2, IL-4, IL-6, and INFγ production, consistent with a predominantly Th2 instead of a Th1 cytokine response.[320] The levels of IL-2 and sIL-2R were found to be lower in some hematological malignancies (Hodgkin's lymphoma and non-Hodgkin's lymphoma).[344]

Down regulation of IL-2 synthesis is associated with the use of immunosuppressive agents, including hydrocortisone, cyclosporin A, Tacrolimus, and cyclophosphamide (see Chapter 33). Also, the immunosuppressive macrolide rapamycin inhibits cytokine-driven proliferation of lymphocytes, acting at a later stage of T lymphocyte activation than the related compound Tacrolimus or cyclosporin A, which block IL-2 transcription. However, the effect of rapamycin on the expression of the IL-2Rα (CD25) is less well documented. Thus rapamycin inhibition of T-cell activation may involve not only IL-2–driven proliferation but also suppression of CD25 up regulation.[582]

Therapeutic Activity

IL-2 was the first cytokine to be used in clinical trials for the treatment of human diseases, especially cancer. This use was based on the discovery that LAK cells (obtained by the stimulation of resting lymphocytes with IL-2) have cytotoxic action against tumor cells while sparing normal cells.[485] IL-2 synergizes with IFNγ and TNFα in a range of antitumor effects but is unique in its ability to mediate activation and expansion of antitumor lymphocytes.[472] However, direct IL-2 therapy (either intravenously or subcutaneously) was only achieved after recombinant IL-2 became available, enabling the use of the large amounts of cytokine required for high-dose therapy in humans (see previous section). These results were limited by the extreme toxicity of IL-2, which affects cardiovascular, respiratory, renal, and hepatic function.[485] The toxic effect of IL-2 depends on the dose and the mode of administration. In the majority of patients, parainfluenza symptoms appear. Most undesirable effects are connected with a multisystemic syndrome of capillary vessel hyperpermeability, leading to increased fluid retention into extravascular spaces, edema, hypotonia, and oliguria.[441] Some of these secondary reactions are in part due to the cytokine cascade effect with production of IFNγ and TNFα.[436] Because of this problem and the relative lack of success with LAK cells, a new regimen of using IL-2 with TIL has been attempted. These cells are 50 to 100 times more potent against homologous tumors than LAK cells. However, despite TIL being found in most human infiltrating ductal breast carcinomas where they should be capable of both in vitro and in vivo activation by IL-2 to produce selective tumor cytolysis, it was observed that the TIL population shows a deficiency in IL-2 and IL-2R expression. This may explain the relative anergic state of native TIL.[100] IL-2R also has been used as a target for IL-2 when coupled with toxins promoting selective cell death.[485] In myelodysplastic syndromes, the in vitro effects of IL-2 suggest the clinical usefulness of this cytokine in a large subgroup of patients, because it may reduce the percentage of blasts and increase clonogenic capacity and cell-mediated cytotoxicity.[99]

Another field of therapeutic interest is the use of IL-2 in immunomodulation, acting as a recovery agent in some immunodeficient conditions, such as that resulting from the administration of immunosuppressive agents.[485] This immunoenhancing capacity in addition has considerable potential for promoting adequate responses to vaccines.[472] As previously mentioned, the use of antibodies against IL-2 or IL-2R subunits can block the activity of this cytokine associated with promising results in the prevention of allograft rejection.[472]

In addition to these uses, IL-2 has been found to be effective in the treatment of patients with disseminate cancer of the kidney and melanoma and in adjuvant therapy of acute myeloid leukemia. Attempts have been made to apply it in the treatment of AIDS and leprosy.[441] The most common areas for IL-2 therapy are renal cell carcinoma,[198] melanoma, and lymphoma.[472,485]

INTERLEUKIN-3

Interleukin-3 (IL-3) is a lymphokine produced by antigen- or mitogen-activated T lymphocytes that stimulate proliferation of hematopoietic and lymphoid stem cells. It is also a colony stimulating factor for all bone marrow progenitor cells.[289] IL-3 supports the growth and differentiation of early hematopoietic and lymphoid stem cells and that of more mature hematopoietic cells, including granulocytes, macrophages, and mast cells.[138]

Synonyms

IL-3 was formerly known as burst promoting activity (BPA), colony forming unit (CFU) stimulating activity, colony stimulating factor (CSF) 2α and 2β, eosinophil-CSF (E-CSF), hematopoietic cell growth factor (HCGF), hemopoietin-2, histamine-producing cell stimulating factor, mast cell growth factor (MCGF) multicolony stimulating factor (M-CSF), multilineage colony stimulating factor, multilineage hemopoietic growth factor, P cell–stimulating factor activity, panspecific hemopoietin, persisting (P) cell–stimulating factor, pluripotential hematopoietic cell stimulating activity, stem cell activating factor, synergistic activity, Thy-1 inducing factor, Thy-1 stimulating activity, and WEHI-3 growth

factor. *(Note WEHI is a macrophage-like myelomonocytic leukemia cell line established from inbred BALB/c mice.)*

General Characteristics

IL-3 is a glycoprotein, and glycosylation accounts for most of the heterogeneity of this molecule. Depending on the cleavage position of the precursor polypeptide, there are two mature forms of IL-3: a protein with 134 or 140 amino acid residues.[152] The half-life in the blood is estimated at about 40 minutes. Its structure is a compact globe with four α-helical short chains.

IL-3 stimulates the growth and differentiation of all hematopoietic lineages rather than self-renewal of primitive stem cells.[71,472] Activated T cells secrete IL-3, but its effects are normally restricted to local cellular activation or to nearby sites where T cells migrate (paracrine action).[152]

Other general characteristics of IL-3 include:

Molecular Weight

Depending on the extent of glycosylation, the literature values for the molecular weight of IL-3 vary from 15 to 32 kDa. The following molecular weights have been reported: 15 kDa,[421] 17 kDa,[472] 14 to 30 kDa,[71] 20 to 26 kDa,[152,436,485] and 20 to 32 kDa.[341,389]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-3 is 29%.[71] There is no cross-species reactivity.

Chromosomal Location

The chromosomal locations of IL-3 and its receptor are 5q23-31 (IL-3); in this area are located the genes of several hematopoietic growth factors, such as GM-CSF, M-CSF, and the M-CSF receptor (known as the c-*fms* oncogene)[485]; Yp13.3, Xp22.3 (IL-3Rα-chain); and 22 (IL-3Rβ-chain).

Cellular Origin

CD4 T cells of both the Th1 and Th2 subsets are the principal source of IL-3 (Figure 22-12), but NK cells, mast cells, eosinophils, possibly keratinocytes, and thymic epithelium and neuronal cells can also produce this cytokine. GM-CSF and IL-3 are generally thought to be produced in a coordinated fashion by all activated T cells, but studies have indicated that T cells have the potential to display diversity of expression of GM-CSF and IL-3.[167]

Control of Synthesis and Release

IL-3 does not exist in a preformed state, being synthesized after cellular activation. Glucocorticoids and cyclosporin A inhibit IL-3 production by T lymphocytes.[472]

Receptor (IL-3R)

The IL-3 receptor is a heterodimeric structure with high- and low-affinity configurations consisting of two chains (subunits): IL-3Rα (CD123 is a 70 kDa peptide) and IL-3Rβ (150 kDa) signal-transducing subunit, shared with IL-5 and GM-CSF, but does not itself bind any of these cytokines.[71] The α-chain is a member of the hematopoietin receptor superfamily, which includes receptors for IL-2, IL-4, IL-6, IL-7, G-CSF, and GM-CSF and consists of a unique WSXWS-containing subunit.[1,472] IL-3, IL-5, and GM-CSF receptors belong to the cytokine receptor superfamily and are structurally and functionally related; thus these constitute a distinct subfamily.

It has been demonstrated that human IL-3 induces heterodimerization of IL-3Rα- and β-chains and that disulfide linkage of these chains is involved in receptor activation but not high-affinity binding. This may also be applicable to the related GM-CSF and IL-5 receptors.[498] IL-3 down regulates the expression of IL-3 receptor, providing a negative feedback control of its activity.[472] IL-3R is present on progenitor cells, monocytes, pre-B cells, and B cells.[71]

Signal Transduction

Signal transduction requires the presence of the β-chain. IL-3–IL-3R interaction results in rapid phosphorylation of several cellular proteins, including the IL-3Rβ-subunit itself.[71]

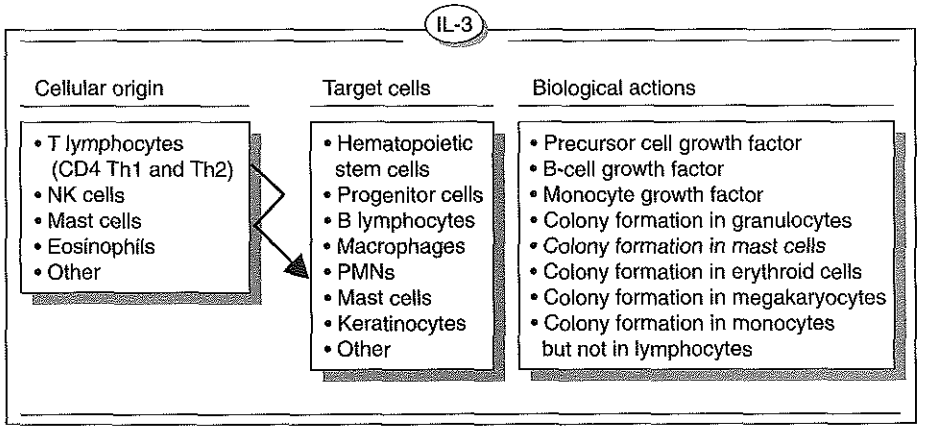

Figure 22-12 Cellular origin, principal target cells, and biological actions of IL-3.

Biological Actions

Effector targets of IL-3 are (1) the pluripotential hematopoietic stem cells and progenitor cells and (2) the other several mature cells, such as B lymphocytes, macrophages, basophils, eosinophils, mast cells, and keratinocytes.[472]

Most functional analyses of IL-3 have been performed in mice and in experimental systems of hematopoiesis. In humans, it has been difficult to establish a role for this molecule. However, many actions attributed to murine IL-3 appear to be performed by human GM-CSF.[1] IL-3 also acts on hematopoietic progenitors, stimulating formation of granulocytes, macrophages, NK cells, erythroid and multipotent precursors, and megakaryocytes, and has biological actions on mast cells, basophils, eosinophils, and macrophages.[341,485] It is thought that IL-3 acts synergistically with IL-1 and IL-6 in the initial phase of erythroid, megakaryocytic, and myelomonocytic development.[436] IL-3 is a broader CSF than more specialized ones, including GM-CSF, G-CSF, and M-CSF. IL-3 seems to cooperate with these factors, providing a very important link between the hematopoietic and immune systems; biological functions of IL-3 are enhanced or depend on the co-stimulation with other cytokines.[71,472] In this manner, the hematopoietic system provides important auxiliary and accessory cells fundamental for an efficient immunoinflammatory reaction.[152] For example, maintenance of local levels of IL-3 is required to (1) increase mast cell in vivo numbers, (2) act as a growth factor for B lymphocytes, and (3) serve as an activator of monocytes.[71,152] Unfortunately, these functions can lead to vascular leak syndrome with extensive hemorrhage, peripheral neuropathy, and reactive erythrophagocytosis as unusual complications of recombinant IL-3 therapy. They suggest a causal mechanism based on the excessive stimulation of macrophages and production of secondary cytokines, such as TNF.[231] The demonstration that T-cell–derived IL-3 induces the production of IL-4 by non-B, non-T cells suggests that IL-3 may amplify the Th2-cytokine response in mice.[291] Also, IL-3 (like IL-4, IL-5, and IL-6), which is mainly produced by Th2 lymphocytes, may possibly regulate the functions of human mast cells in vivo via specific receptors in allergic reactions.[584]

Clinical Significance

Excessive production of IL-3 has been described in several pathological conditions, especially in monocytic or myeloid leukemias and mast cell disorders.[472] However, IL-3 can be measured in blood only after severe immunological stimuli, such as graft-versus-host disease or parasitic infestations. IL-3 may also play an important role in chronic allergic diseases.[152,584]

Therapeutic Applications

IL-3 has been used in clinical trials designed to assess the benefit from hematopoietic stimulation, shortening the duration of cytopenias associated with chemotherapy or irradiation, or following bone marrow transplantation.[472,485] However, the use of IL-3 (GM-CSF or IL-6) to reduce myelosuppression after high-dose chemotherapy appears unlikely to result in stimulation of the growth of the most common solid tumors.[236]

INTERLEUKIN-4

Interleukin-4 (IL-4) is a lymphokine produced by antigen- or mitogen-activated T cells; its principal role is regulation of IgE- and eosinophil-mediated immune reactions. It stimulates switching of B cells for production of IgE. It is a growth and differentiation factor for T cells, particularly Th2 cells; is a growth factor for mast cells; and stimulates the expression of some adhesion molecules on endothelial cells.[138]

Synonyms

IL-4 has been formerly known as B-cell differentiating factor (BCDF), B-cell growth factor I (BCGF-I), B-cell stimulating factor I (BSF-I), MCGF-II, and T-cell growth factor II (TCGF-II).

General Characteristics

IL-4 is a member of the four α-helical short-chain cytokine family. The three-dimensional structure is a compact globe with a predominant hydrophobic core.[71]

IL-4 is a pleiotropic cytokine as demonstrated by the range of cells expressing the IL-4 receptor. IL-4 production is now used as a criterion for classifying CD4 T cells into the Th2 subset. It plays a critical role in IgE- and eosinophil-mediated immunoinflammatory reactions. It is also a growth and differentiation factor for lymphocytes and an antiinflammatory molecule that modulates the biological action of macrophages.[1,436]

Molecular Weight

Depending on the degree of glycosylation, the literature values for the molecular weight of IL-4 vary from 15 to 20 kDa. The following molecular weights have been reported: 18 to 20 kDa,[341,389] 20 kDa (monomer),[1,152,421] 15 kDa (glycoprotein),[472] and 15 to 19 kDa.[71]

Cross-Reactivity

The cross-reactivities (amino acid sequence homology between human and mouse) for different forms of IL-4 include[71,52]:

IL-4 (amino acids 1 to 90 and 129 to 149)—50%

IL-4 (amino acids 91 to 128)—very little

IL-4 is species specific (human IL-4 has no activity on mouse cells and vice versa)

Chromosomal Location

The chromosomal locations of IL-4 and its receptor are 5q23-31 (IL-4), and 16p12.1-11.2 (high-affinity receptor).

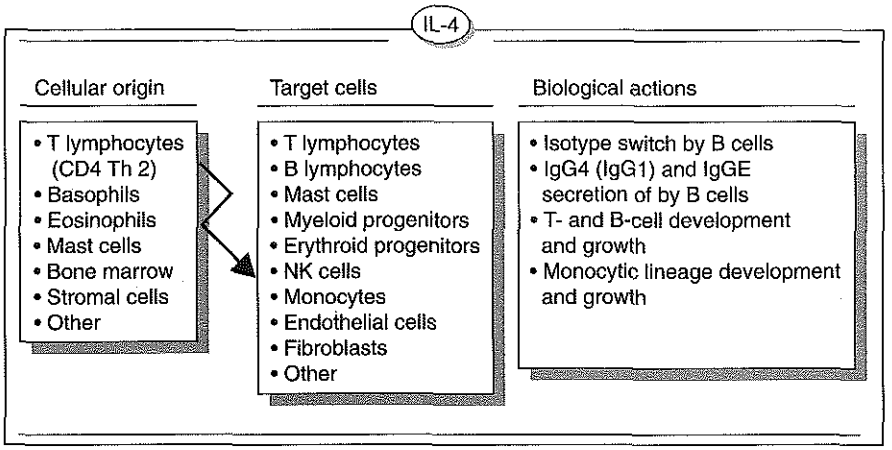

Figure 22-13 Cellular origin, principal target cells, and biological actions of IL-4.

Cellular Origin

IL-4 is synthesized by subtype Th2 of T lymphocytes, basophils, eosinophils, and mast cells and bone marrow stromal cells (Figure 22-13). Some CD8 T cells also produce IL-4.[1,494,584]

Control of Synthesis and Release

IL-4 production depends on T-cell activation or cross-linking of IgE receptors (FcεRI and FcεRII) on mast cells and basophils. In vitro addition of IL-2 or IL-15 to cultures of naive CD4 T cells has differential effects on priming for IL-4. In addition, IL-15 does not restore priming for IL-4, suggesting that IL-2 and IL-15 may have different functional properties during the in vitro differentiation of IL-4–producing cells.[469] It has been suggested that IL-4 synthesis is induced in normal T lymphocytes in the absence of exogenous IL-4 and that CD40L co-stimulation is of fundamental importance in regulation of IL-4 production.[56] This provides a mechanism by which B cells preferentially enhance IL-4 synthesis in T cells at low antigen concentrations.[56] However, it has also been found that CD40-mediated stimulation contributes to lymphocyte proliferation, antibody production, eosinophilia, and mastocytosis during an in vivo Th2 response. IL-4 is not required for T-cell IL-4 production.[333] IL-8 may be an important regulator of CD4 T-cell–derived IL-4, thereby possibly regulating the balance between humoral and cellular T cell-dependent responses.[186] T-cell–derived IL-3 induces the production of IL-4 by non-B, non-T cells to amplify the Th2-cytokine response.[291] No correlation has been found among IL-2-, IL-4-, and IFN-secreting cells, indicating that the production of preponderantly T-cell–derived cytokines is regulated independently.[205]

Production of IL-4 by T cells is induced by mitogens and antigens and suppressed by TGFβ and cyclosporin A. Also, IL-4 expression in T lymphocytes is selectively inhibited by IL-1α and IL-1β; this interaction may represent an important physiological regulator of the balance between proinflammatory cytokines from activated macrophages and antiinflammatory cytokines from T cells.[457] Prednisolone-treated patients show a reduction of the number of cells expressing IL-4.[38] Thiols, usually administered to humans as a mucolytic agent, decrease IL-4 production and IL-4–induced Ig synthesis.[244] Vasoactive intestinal peptide inhibits IL-4 production at a posttranscriptional level. Studies have probed the molecular mechanisms involved in the neuroendocrine regulation of cytokine production.[561] The results support the idea that neuropeptides may participate in the intricate cytokine network controlling local immune responses. Usually IL-4 is a neosynthesized molecule, with the exception of mast cells that contain IL-4 in a preformed state.[472]

Receptor (IL-4R)

The IL-4 receptor is a molecular complex consisting at least of two chains: a high-affinity IL-4 binding chain (p140, α-chain, CD124) and the IL-2R γ-chain also known as the common γ-chain (γc, p64). The high-affinity IL-4 binding chain belongs to the cytokine receptor superfamily and contains the conserved WSXWS motif. The γ-chain is a functional component of the IL-4R and augments IL-4 binding affinity. However, IL-4 does not use or require the common γc of the IL-2R on human endothelial cells to mediate vascular cell adhesion.[465] A soluble form of IL-4R has been found to be a potent IL-4 antagonist.

Monomeric high-affinity IL-4 receptors (CD124) are found on T and B cells, macrophages, mast cells, muscle cells, neuroblasts, stromal cells (brain and bone marrow), myeloid cells, granulocytes, megakaryocytes, hematopoietic progenitor cells, NK cells, fibroblasts, and epithelial and endothelial cells.[152,341] About 300 IL-4 receptors per cell are found on B and T lymphocytes, a number that increases to 100 to 1000 receptors per cell with cell maturation and activation.[71,152]

A second low-affinity IL-4 receptor has also been identified and appears to be coupled to a different signal transduction pathway.[71]

Signal Transduction

IL-4 signaling may involve clustering of the receptor-associated tyrosine kinase and IL-4 binding to the CD124 receptor, resulting in tyrosine phosphorylation of cellular proteins. Activation of tyrosine phosphatase and dephosphorylation of an 80-kDa protein have also been reported. Another signal transduction pathway has been shown to involve breakdown of phosphatidylinositol bisphosphate. This pathway may be coupled to a low-affinity receptor.[1,71] Tyrosine phosphorylation of STAT6 is activated in response to IL-4 and may contribute to various functions, including mitogenesis, CD4 lymphocyte differentiation, and Ig isotype switching, which collectively play a central role in exerting IL-4–mediated biological responses.[480,513]

Biological Actions

The principal functional targets of IL-4 are T cells, B cells, monocytes, endothelial cells, fibroblasts, mast cells, and myeloid and erythroid progenitors. IL-4 (1) induces growth of these cells, (2) promotes class isotype switching in B cells to IgE (keeping up with induced expression of IgE receptors), and (3) augments IgG4 (IgG1 in mouse) production. IL-4 also induces biological responses in other cells, such as NK cells, fibroblasts, and endothelial cells.[341,436]

IL-4 also has the capacity to drive CD4 T-cell differentiation to the Th2 type, thereby blocking Th1 development. This creates a bias in the immune response, with a deleterious effect on the defense capacity against certain biological aggressors, such as intracellular pathogens. Alternately, consequent IgE switching is associated with exacerbated antibody production (especially IgE and IgG classes), immediate hypersensitivity reactions, and defense against helminthic infections (one of the few known physiological functions of the Th2 polarization of CD4 T cells in humans). As a Th2 stimulator, IL-4 inhibits macrophage activation and blocks most of the activating effects of IFNγ, including IL-1, nitric oxide (NO), and PG production. These effects are shared with those of IL-10 (also produced by Th2 cells), resulting in suppression of macrophage-mediated immune reactions. Early IL-4 production after antigen exposure favors the Th2 polarization, further promoting expansion of this T-cell subset because an autocrine growth factor.[1,451] The origin of IL-4 (as a critical element in the induction of Th2 response) during a primary immune response is not yet well defined,[450] although the class I-selected CD4neg CD8neg TCRαβ T cells (double negative CD3 cells) are being proposed as a novel source of this cytokine.[309,310] However, it has been demonstrated that naive human CD4 T cells release low but sufficient levels of IL-4 at priming to support their development into IL-4 producers.[586] IL-4, in the absence of antigen stimulation, induces an anergy-like state in differentiated CD8 Tc1 cells, suppressing IL-2 synthesis and autonomous proliferative pathway but retaining of cytotoxicity and synthesis of other cytokines.[451]

In addition, IL-4 exerts two key regulatory effects in inflammation[472]:

1. It promotes adhesion of lymphocytes (in preference to neutrophils) to endothelial cells, stimulating the expression of adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1). IL-4 also induces secretion of CKs by endothelial cells, resulting in an inflammatory response with the attraction of monocytes and eosinophils.[1] Constitutive production of IL-4 itself (also IL-8 and IL-10) by normal peripheral blood eosinophils represents an important role in modulating immune responses in diseases associated with eosinophils and favors Th2 polarization[370,382] amplified by the possibility of enhanced expression of Fcγ RIα by IL-4.[522] The preferential promotion of a lymphocyte's adhesion may hasten the transition from acute neutrophil-dominated to chronic lymphocyte-dominated inflammation. Surprising is the demonstration that the CK growth-regulated oncogene-α (GROα) that induces T lymphocyte chemotaxis* is inhibited by IL-4, IL-10, and IL-13.[245] Alternately, IL-4 may have a protective vascular effect down regulating fibrinogen production.[551]
2. IL-4 induces an antiinflammatory effect by its ability to suppress production of proinflammatory cytokines (IL-1, TNFα, and IL-6) and to favor the release of IL-1RA.[345,360] This antiinflammatory action is evident on activated monocytes and/or macrophages, namely the inhibition of IL-6 production.[132,514] Indeed, not all target cells may be influenced in this way (e.g., IL-4 may be capable of regulating intestinal epithelial cell proliferation without altering the capacity of these cells to function in the inflammatory response by secreting IL-6).[353] IL-4 and IFNγ also synergistically increase total polymeric IgA receptor levels in human intestinal epithelial cells.[126]

Pleiotropic activities of IL-4 include (1) increased class II MHC antigen expression on B cells, (2) enhanced G-CSF–induced proliferation of granulocyte-macrophage precursors, (3) inhibition of LAK cell induction, and (4) synergism with IL-3 and IL-9 in stimulating mast cell and basophil proliferation.[1,152,341,436] IL-4 and IL-13 inhibit bone resorption by suppressing cyclooxygenase-2–dependent PG synthesis in osteoblasts.[400] IL-4 and IL-1β may contribute to the enhanced synthesis of collagen and consequent fibrosis, regulating its production in human skin, liver, and lung fibroblasts.[528]

IL-12 is considered as a counterbalancing cytokine to IL-4 as it cross regulates it.[341] IL-13 has been identified as having

*Chemotaxis is the orientation of a cell along a chemical concentration gradient or movement in the direction of the gradient, either toward (positive chemotaxis) or away from (negative chemotaxis) the greater concentration of the substance, referred to as a chemotactic factor, chemotactin, or chemoattractant. Macrophages, neutrophils, eosinophils, and lymphocytes exhibit chemotaxis in response to a wide variety of substances released at sites of inflammatory reactions, including lymphokines, mediators released by basophils and mast cells, bacterial products, and C5a and other activated complement components.

overlapping biological activities with IL-4, supporting the hypothesis that the two cytokines use a common receptor complex or signal pathway.[124]

Clinical Relevance

IL-4 is the main physiological regulator of allergic reactions (immediate hypersensitivity). As IL-4 boosts immune mechanisms that rely on IgE (that include antigen recognition by mast cells and epidermal Langerhans' cells), excessive production of it is associated with disorders in which these cells are pivotal, such as atopic dermatitis.[472] IL-4 also plays a key role in the contact sensitivity skin reaction.[17] It has been postulated that in atopic patients, IL-4 is the most discriminatory cytokine and that the level of serum IgE has a low predictive value in allergic disease.[157] In this study, because of a lack of correlation between IL-4 and serum IgE, the authors suggest that the measurement of IL-4 in blood mononuclear cells may be of great value in the analysis of allergic responses in atopic donors. Excessive production of IL-4 is associated with T-cell lymphomas (Th2 subtype), also with a corresponding strong expression of the low-affinity receptor for IgE (CD23).[472]

Therapeutic Applications

IL-4 may be useful in the therapy of humoral immunodeficiency.[485] In addition, it has antitumor effects on some solid tumors because it can initiate cytotoxic responses mediated by eosinophils, macrophages, and T lymphocytes, and this activity may be useful in the clinical setting.[341,365,472] Experimental models of vaccination with tumor cells engineered to produce IL-4 have shown that the local release of this cytokine is associated with the development of antitumor immunity that may induce regression of established cancer.[359] IL-4 can also modify integrin expression and adhesive functions of tumor cells in vitro, acting as direct regulators of adhesive mechanisms of tumor cells bearing adequate receptors, thus influencing metastasis.[215]

Anti–IL-4 antibodies could be interesting as a means of correcting the balance between Th1 and Th2 cells in Th2 polarized situations.[341] However, it has been reported that the peripheral blood of allergic individuals contains long-lived allergen-specific B cells that have already switched to IgE production and that are not sensitive to IL-4 and IL-13 treatment. These results may have implications on attempts to use cytokines or cytokine antagonists in therapy of a type I allergy.[133]

In an attempt to develop additional antiviral therapeutic strategies, De Francesco and colleagues have found that HIV-1 p17 matrix protein greatly increased HIV-1 replication in preactivated peripheral blood mononuclear cell cultures obtained from healthy donors.[116] In their studies they have discovered that p17 exerts its biological activity after binding to a specific cellular receptor expressed on activated T-enhancing levels of TNFα and IFNγ released from cells stimulated by IL-2. IL-4 was found to down regulate IFNγ and TNFα, and p17 restored the ability of cells to produce both cytokines. The property of p17 to increase production of proinflammatory cytokines could be a mechanism exploited by the virus to create a more suitable environment for HIV-1 infection and replication.

INTERLEUKIN-5

Interleukin-5 (IL-5) is a lymphokine produced by antigen- or mitogen-activated T cells and by activated mast cells that stimulates the growth and differentiation of eosinophils and activates mature eosinophils to kill helminths. It may act as a cofactor in the growth and differentiation of B cells and may also be involved in increasing synthesis of IgA by mature B cells.[138]

Synonyms

IL-5 was formerly known as BCDF B-cell differentiation factor for IgM (BCDFμ), B-cell growth factor II (BCGF-II), eosinophil colony stimulating factor, eosinophil differentiation factor, IgA-enhancing factor, and T-cell replacing factor (TRF).*

General Characteristics

IL-5 is an antiparallel disulfide-linked homodimer (115 AA). It belongs to the four α-helical short-chain cytokine family with two short β-sheets. The novel dimeric structure is considered unique, containing four helices (A to D) arranged in an up-up-down-down topology. In contrast to other subfamily members, which fold unimolecularly into a single helical bundle, IL-5 forms a pair of helical bundles by the interdigitation of two identical monomers that contribute a D helix to the others' A through C helices.[1,72,127,128,341] The monomer is biologically inactive. It has been predicted that the lack of bioactivity by IL-5 monomer is due to a short loop between helices C and D, which physically prevents unimolecular folding of helix D into a functionally obligate structural motif. By lengthening this loop, an insertional mutant of IL-5 is engineered that is expressed as a monomer with biological activity similar to that of native IL-5. These studies demonstrate that all of the structural features necessary for IL-5 to function are contained within a single helical bundle.[128] Dimerization of this glycoprotein possibly enables enough affinity interaction with the receptor. IL-5 is a cytokine typically produced by the Th2 subset of CD4 T cells and by activated mast cells, having as major activity the stimulation of growth and differentiation of eosinophils and the activation of mature eosinophils.[1,26,71]

Other general characteristics of IL-5 include:

Molecular Weight

Depending on its molecular form, the literature values for the molecular weight of IL-5 vary from 18 to 45 kDa. The following molecular weights have been reported: 24 kDa

*TRF means a factor that could replace T lymphocytes in the stimulation of B lymphocytes to produce antibodies, without MHC restriction and antigen-specific stimulus.

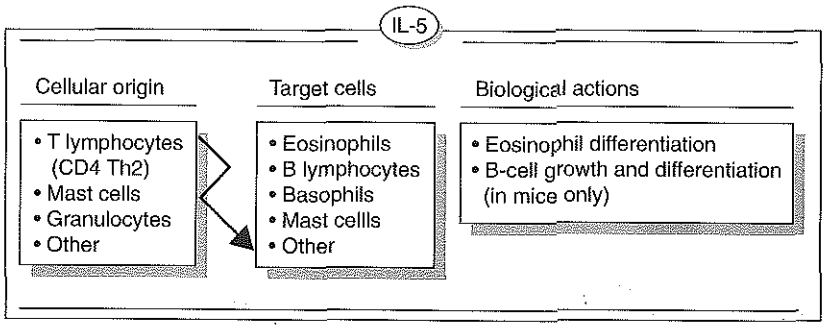

Figure 22-14 Cellular origin, principal target cells, and biological actions of IL-5.

(as a disulfide bonded dimer),[341] 40 kDa homodimeric cytokine,[1,152] 45 kDa,[71,421] 18 kDa,[472] and 40 to 45 kDa.[389]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-5 is 71%.[71] There is a significant cross-reactivity in functional assays.

Chromosomal Location

The chromosomal locations of IL-5 and its receptor are 5q23-31 (IL-5) and 3p26 (IL-5R).

Cellular Origin

IL-5 is produced by the activated Th2 subset of CD4 T cells, mast cells, and eosinophils (Figure 22-14).

Control of Synthesis and Release

Parasitic (helminths) and bacterial infections provide a major stimulus for IL-5 secretion by activated T cells (CD4 Th2) and mast cells. It has been demonstrated that naive human CD4 T cells release low but sufficient levels of IL-4 at priming to support its clonal expansion into high IL-4 and/or IL-5 producers.[586] IFNα selectively down regulates IL-5 synthesis by human CD4 T cells.[462] Prednisolone treatment in asthma is associated with reduction in the number of cells expressing mRNA for IL-5.[38] Cyclosporin A reduces the expression and production of IL-5.[235]

Experimental data suggest that activation via the unique sequence combination GATA/CLE0 results in selective expression of the IL-5 gene in response to elevated levels of intracellular cyclic adenosine monophosphate (cAMP).[484]

Receptor (IL-5R)

The IL-5R complex has a specific low-affinity ligand binding chain of 55 kDa (CD125), containing the WSXWS motif, and a nonbinding β-chain (βc) with 150 kDa (common to IL-3R and GM-CSFR); the latter can convert the low-affinity IL-5R into the high-affinity IL-5R and is indispensable for IL-5 signal transduction. Both chains belong to the cytokine receptor superfamily. Soluble forms of IL-5R are produced with unknown significance, unless they modulate IL-5–dependent eosinophilia in humans.* IL-5 receptor is expressed on eosinophils, basophils, and activated murine B cells. These cells display 500 to 1000 low-affinity receptors and 7500 to 10,000 high-affinity receptors per cell.[152] A controversy exists about the expression and biological significance of IL-5R in human B lymphocytes. However, IL-5 can regulate human B cells but only if they have been appropriately stimulated to undergo terminal differentiation.[233]

*References 1, 26, 64, 71, 152, 341, 512.

Signal Transduction

Although not completely elucidated,[71] studies have suggested that JAK2 kinase and an activated isoform of mitogen-activated protein (MAP) kinase, p45, may mediate some of IL-5's effects. This mediation occurs on eosinophils in a manner unique to the activation pathways previously described for other cells.[31,512]

Biological Actions

An important difference between murine and human IL-5 is that murine IL-5 causes B-cell and eosinophil differentiation, while human recombinant IL-5 causes only eosinophil differentiation and regulates IgA isotype selection.[71,152,200]

As in B cells, IL-5 has a very important role in the production of IgA based on a late-acting B-cell differentiation (although IgA synthesis is probably the result of synergistic actions with other cytokines, such as IL-6). However, on B cells, IL-5 (1) can be a co-stimulator for the growth of antigen-activated B cells; (2) may function synergistically with other cytokines, such as IL-2 and IL-4, to stimulate the growth and differentiation of these cells; (3) can induce the expression of IL-2R; (4) can promote IgG and IgM secretion; and (5) can enhance the expression of CD23 and the synthesis of IgE (these two synergistically with IL-4). The general effect of IL-5 on B cells is essential for the proper function of eosinophils during the immune response to infection.[472] In particular, IL-5 plays a critical role in the development of CD5-positive B (B-1) cells.[512]

IL-5 has a recognized effect on eosinophil growth, differentiation, and chemoattraction (inducing the generation of eosinophils from bone marrow precursors, up regulating the expression of CD11b, and activating IgA-induced degranulation).[341,472] Eosinophilia is a uniquely specific phenomenon regulated by IL-5, suggesting specific control for IL-5 gene expression.[257] The activity of IL-5 on eosinophils is

complemented by the activities of IL-4 (IgE switching and eosinophil recruitment) and of IL-10 (IgG4 switching), contributing to Th2-mediated allergic reactions.[1,70]

IL-5 also enhances the expression of IL-2R on B cells and stimulates basophils.[341,472] Proeosinophilic and/or proallergic Th2 cytokines, originally described as T lymphocyte products, have been ascribed to mast cells as well, and these cells are probably analogous to T cells in the requirement of costimuli for the production of IL-5 protein. Moreover, the rapid kinetics of IgE-mediated IL-5 transcription and protein elaboration are consistent with a primary role for mast cell activation, directly leading to late phase airway eosinophilia.[240]

Clinical Relevance

IL-5 is a key molecule in allergic diseases. For example, the late manifestations of the allergic response in asthmatic patients are associated with eosinophil accumulation in the lung. These granulocytes are implicated in lung damage through release of the eosinophil's major basic protein and neurotoxin.[302,341] The eosinophilia results from T-cell activation (namely CD4 cells),[530] secretion of IL-5, and consequent increase of eosinophil concentration. Compared with patients with adult respiratory distress syndrome, the patients with acute eosinophilic pneumonia had high bronchoalveolar lavage fluid levels of IL-5, IL-1RA, and soluble type II IL-1R but not IL-1β, TNFα, IL-3, or GM-CSF.[6] A 1995 study demonstrated that mononuclear cells from HLA-B8 DR3-positive individuals display a reduction of IL-5 production, suggesting that the IgA synthesis dysregulation (IgA deficiency) observed in HLA-B8 DR3-positive individuals could be due to an impairment of IL-5 production.[324] The expression and production of IL-5 are high in severe atopic dermatitis.[235] Global studies suggest that IL-3, IL-4, IL-5, and IL-6, which are mainly produced by T helper 2 lymphocytes, might regulate the functions of human mast cells in vivo via specific receptors in allergic reactions.[584]

Therapeutic Applications

IL-5 may be useful for the therapy of hypogammaglobulinemia.[485] There is some promise in the clinical setting for treating helminth infections (enhancement of antibody-dependent cell-mediated cytotoxicity; ADCC), as a pivotal molecule in the stimulation of growth and differentiation of eosinophils, and in the activation of mature eosinophils to kill helminths.[152,472] A detailed understanding of IL-5 structure and function is required to develop immunomodulators of IL-5–mediated inflammatory responses (as in asthma and allergic diseases), particularly the A/D helical region of this cytokine.[128]

INTERLEUKIN-6

Interleukin-6 (IL-6) is a lymphokine produced by antigen- or mitogen-activated T cells, fibroblasts, macrophages, and other cells that serves as a differentiation factor for B cells and thymocytes and stimulates immunoglobulin production by B cells; it also induces hepatocytes to synthesize various plasma proteins involved in the acute phase response (APR) and is a cofactor in initiation of the cell cycle in primitive hematopoietic cells in vitro.[138]

Synonyms

IL-6 was formerly known as 26-kDa protein, BCDF, B-cell stimulating factor 2 (BSF-2), cytotoxic T-cell differentiation factor, hepatocyte differentiation factor (HSF), hybridoma/plasmacytoma growth factor, interferon-β2 (IFNβ2), monocyte granulocyte inducer type 2 (MGI-2), and thrombopoietin. The designation of IFNβ-2 is now considered inappropriate, and its use has been discontinued.[1,71,472]

General Characteristics

The molecular configuration of IL-6 is not completely known.[71] However, it is known to belong to the four α-helical long-chain family. It is known to be a pleiotropic cytokine produced by many types of cells (lymphoid and nonlymphoid) and affecting diverse biological areas (regulation of T- and B-cell function, Ig secretion, acute phase inflammatory reactions, and hematopoiesis).[71,421] Like IL-1 and TNFα, IL-6 is a participant in a cytokine cascade that regulates the immunoinflammatory response to infection, assuming a very important role in host defense.[152,472]

Other general characteristics of IL-6 include:

Molecular Weight

The literature values for the molecular weight of IL-6 vary from 20 to 29 kDa. The following molecular weights have been reported: 21 to 26 kDa,[341,389] 26 kDa (homodimer),[1,71,421,436,472] and 20 and 29 kDa.[152]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-6 is 42%.[71] Human IL-6 is functional on mouse cells, but murine IL-6 has no activity on human cells.

Chromosomal Location

The chromosomal locations of IL-6 and its receptor are 7p21-14 (IL-6), 1 (IL-6Rα), and 5 and 17 (gp130).

Cellular Origin

IL-6 is secreted by a wide variety of cells, including T and B lymphocytes,* monocytes and/or macrophages, fibroblasts, endothelial cells, epithelial cells, mast cells, neuronal cells, astrocytes, microglia, mesangial cells, osteoblasts, epidermal Langerhans' cells, dendritic cells, and keratinocytes and bone marrow stromal cells (Figure 22-15).†

*Loss of IL-6 secretion is a functional characteristic of human germinal center B lymphocytes. The change from an autocrine to a paracrine IL-6 response may permit a better control of B-cell growth and differentiation during the germinal center reaction.[68]

†References 1, 152, 288, 299, 341, 406.

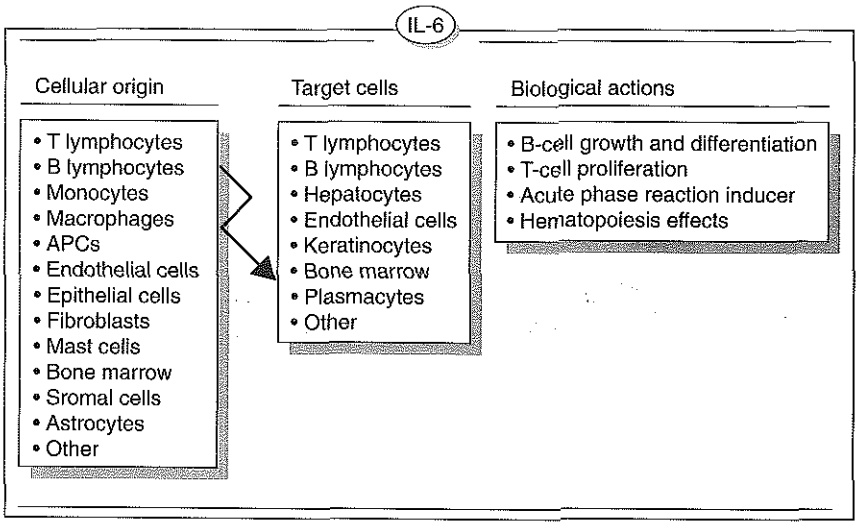

Figure 22-15 Cellular origin, principal target cells, and biological actions of IL-6.

Control of Synthesis and Release

Endotoxins, IL-1 and, to a lesser extent, TNFα are enhancers of IL-6 secretion.[1,152,472] However, studies have demonstrated that unlike TNF, IL-1 does not cause neutrophil degranulation in humans despite its ability to cause neutrophilia and the rapid release of IL-6 and IL-8.[395] Eosinophil major basic protein interacts in a synergistic fashion with IL-1α or TGFβ to augment fibroblast IL-6 type of cytokine production.[443] CD40 ligand triggers IL-6 secretion and related cellular differentiation and primes B cells for responsiveness to IL-10 with a consequent increase of Ig secretion.[543] The subcellular component of type III group B streptococci (GBS) is a potent inducer of IL-6 and may play an important role in tissue inflammation during GBS infection.[546] The complement activation fragment C5a has been shown to induce IL-6 synthesis by peripheral blood mononuclear cells (PBMCs). This may be important in the modulation of IL-6 synthesis in gram-negative bacteremia,[221] particularly because LPS is known to stimulate IL-6 release.

IL-10 and IL-4 inhibit cytokine expression in activated human monocytes, which suggests that IL-4 may inhibit the transcription of the IL-6 gene. IL-10 may inhibit the IL-6 mRNA levels posttranscriptionally, without suppressing promoter activity in human monocytes.[132,514] IL-10 also inhibits the production of IL-6, IL-12, and TNFα.[110] Reduced IL-6 levels in individuals who are exposed to chromate were reported, pointing to its possible role in negative immunomodulation.[490] Also, nitrite (NO^{-2}) induces a decrease of LPS-stimulated IL-1β, IL-6, IL-8, and TNFα release from activated alveolar macrophages.[273]

Receptor (IL-6R)

The IL-6R consists of a noncovalent association of a 60-kDa α-ligand–binding chain subunit (CD126) and a 130-kDa β-signal–transducing subunit (CD130, gp130). The binding protein contains both an Ig domain and a WSXWS motif. The signal transducing subunit does not itself bind IL-6 and also contains both an Ig domain and the WSXWS motif, but it is not specific for IL-6 (shared with IL-11, LIF, and other noninterleukin molecules, such as OSM and CNTF).* IL-6 interacts with the α-ligand–binding chain subunit of IL-6R, initiating interaction with gp130 and its dimerization.[341] However, gp130 transducing receptor cross-linking is sufficient to generate functional IL-6 type responses in hematopoietic, neural, and hepatic cells.[170]

IL-6 receptor has a density of about 50 to 2000 receptors per cell and is expressed on activated B cells (resting B cells do not express the IL-6R but are induced to express it following activation), plasma cells, T cells, monocytes, and many other cells, including epithelial cells, fibroblasts, hepatocytes, and neural cells.[71,152,341] Glucocorticoid-dependent induction of IL-6R expression in human hepatocytes facilitates IL-6 stimulation of amino acid transport, providing the liver with substrate to support key metabolic pathways during catabolic states.[165] Human bronchial epithelial cells constitutively expressed mRNA for IL-6R and IL-1α, and IL-6 itself up regulated IL-6R gene expression; IL-6 might be involved in the regulation of the epithelial functions via an autocrine and a paracrine mechanism.[515] It has also been demonstrated that the IL-11R can serve as a substitute to IL-6R in activating gene expression in target cells that are devoid of the appropriate ligand-binding receptor subunits.[33] Receptors for IL-10 and IL-6 type of cytokines use similar signaling mechanisms for inducing transcription through IL-6 response elements. This demonstrates that the IL-10R, unlike other members of the IFN receptor family, is highly effective in recruiting the signaling pathways of IL-6 type of cytokine receptors.[301] IL-6 has been found to possess three topologically distinct receptor binding sites: site 1 for binding to the subunit-specific chain IL-6Rα and sites 2 and 3 for the interaction with two subunits of the signaling chain

*References 1, 36, 71, 86, 152, 341.

gp130. It may be possible to develop effective IL-6 blocking agents in vivo.[493]

Shed IL-6 receptors (soluble receptors) can also bind IL-6 and signal through the cell-bound gp130 subunit.[1] Because the intracytoplasmic region of the IL-6Rα does not contribute to signaling, soluble forms of the extracytoplasmic domain (sIL-6Rα) potentiate IL-6 bioactivity and induce a cytokine-responsive status in cells expressing gp130 only. This observation, together with the detection of high levels of circulating soluble human IL-6Rα in sera, suggests that the IL-6–sIL-6Rα complex represents an alternative form of the cytokine.[531]

Signal Transduction

IL-6 binds to the IL-6Rα and the IL-6–IL-6Rα complex, which then binds two gp130 molecules to form a gp130 disulfide-linked homodimer, resulting in tyrosine phosphorylation of gp130 and signal transduction. IL-6 has also been shown to induce phosphorylation of the CD40 B-cell receptor.[71,341] Further investigation has revealed that IL-6, but neither IL-4 nor IFNγ, activates the LIL factor. Thus the existence of such a STAT-like factor relates the LPS and IL-1 signaling pathway to other cytokine receptor signaling pathways via the activation of STATs, suggesting that LPS, IL-1, and IL-6 may use a common signaling pathway.[539] IL-6 is the major cytokine-inducing transcription of human CRP during the APR. STAT family members have been shown to be important mediators of the effects of many cytokines—including IL-6, and especially STAT3, which participates in the transcriptional activation of CRP in response to IL-6.[594]

Biological Actions

IL-6 has multifunctional and pleiotropic effects that are summarized in Table 22-5, but its two most extensively studied effects are on B cells and hepatocytes.[1,341]

IL-6 does not induce production of any other cytokines and has relatively little direct effect on immune cells at physiological concentrations, suggesting that its main immunological function is to potentiate the effect of other cytokines.

B Lymphocytes

In activated B cells, IL-6 acts late in the sequence of antigen- or mitogen-driven B-cell differentiation-promoting growth and facilitates maturation-enhancing Ig secretion (growth factor for plasmacytes). IL-6 and IL-10 from Th2 types of cells may play an important compensatory role in the induction and regulation of mucosal IgA responses.[396] IL-6 can also promote in vitro the growth of somatic cell hybrids (hybridomas) that produce monoclonal antibodies, and it acts as a growth factor for myeloma and/or plasmacytoma and Kaposi's sarcoma cells. Other cytokines (IFNs, TNFα, and TGFβ) and possibly other factors are potent, dominant inhibitors of IL-6–dependent plasmacytoma and/or hybridoma growth in vitro.[468]

TABLE 22-5 Principal Biological Activities of IL-6*

Target	Action
Immune System	
B cells	Late growth and differentiation factor (increases IgS production)
T cells	Activation and proliferation (increases IL-2R expression)
	Differentiation of Tc cells
Bone marrow	Enhances hematopoiesis
Hepatocytes	Induces acute phase protein synthesis
Brain	
Pituitary	Increases ACTH
Hypothalamus	Rise of temperature
Astrocyte	Increases nerve growth factor production
Kidney	Increases mesangial proliferation
Endothelial cells	Secretion of IL-1 and TNFα
	Increases adherence for lymphocytes
Keratinocytes	Proliferation
	Secretion of IL-1 and TNFα
Human malignant plasma cells	Chemotaxis-inhibitory effect

*References 1, 37, 109, 341, 468, 477, 566.

Hepatocytes

IL-6 is the principal inducer of the APR, directly acting on hepatocytes to synthesize acute phase proteins, such as CRP, complement components, orosomucoid, haptoglobin, fibrinogen, protease inhibitors, and others. Its effects on the APR involve a complex interaction (namely synergistic actions) with several other cytokines, notably IL-1 and TNF.

T Lymphocytes and Natural Killer (NK) Cells

IL-6 is a co-stimulator of T cells and thymocytes, a differentiation factor for Tc lymphocytes, and a cofactor with other cytokines for the growth of early bone marrow hematopoietic stem cells. IL-10 production is enhanced in human T cells by IL-6 and IL-12.[109] IL-6 augments NK-cell activity (it appears to synergize also with IL-1).

Progenitor and Other Types of Cells

IL-6 synergizes with IL-3 (and probably GM-CSF) to support proliferation of neutrophil, monocyte, eosinophil, and megakaryocyte colonies. Increased mesangial proliferation in the kidney inhibits the growth of fibroblasts and induces class I HLA expression on their cell surfaces.

Endothelial Cells/Chemotaxis

IL-6 acts on endothelial cells to preferentially increase their adherence for lymphocytes (enhanced expression of intercellular adhesion molecule-1 [ICAM-1] and of VCAM-1 and E-selectin). These molecules and the leukocyte integrin LFA-1 all contribute to lymphocyte binding to endothelium activated by IL-6. It is proposed that IL-6 may also be involved in the recruitment of lymphocytes into nonlymphoid tissue.[566]

This cytokine has also been found to have a chemotaxis-inhibitory effect. High levels of IL-6 in the bone marrow microenvironment of patients with multiple myeloma appear to be favorable for the localization of myeloma cells in situ. This capacity to inhibit the chemotaxis of human malignant plasma cells is probably transduced via the signal-transducing receptor component, gp130.[477]

Immunoinflammatory Reactions/Fever

The demonstration that resident epidermal Langerhans' cells and the dendritic cells into which they develop are important sources of IL-6 explains the induction of cutaneous immunoinflammatory responses.[107] Human epidermal keratinocytes are induced to secrete IL-6 and co-stimulate T-lymphocyte proliferation by a CD40-dependent mechanism, amplifying inflammatory processes in the skin.[182] The rapid response in the expression of LIF and IL-6 genes after injury suggests that these cytokines act as trauma factors but with different roles in injured peripheral nerve.[77,295]

In common with IL-1 and TNF, IL-6 has a role as an endogenous pyrogen, inducing fever. It was suggested that central IL-6 is a necessary component of the fever response to both endogenous (IL-1β) and exogenous (LPS) pyrogens in mice and that IL-6 acts downstream from both peripheral and central IL-1β.[80]

Neuroendocrine Axis

IL-6 acts on the pituitary to induce adrenocorticotropic hormone (ACTH) release and directly on the adrenal glands to produce glucocorticoids. It is known that different cytokines that share gp130 as a receptor subunit induce serum amyloid A, and potentiate the induction of IL-6 and the activation of the hypothalamic-pituitary-adrenal axis by IL-1. In particular, LIF, OSM, IL-11, and cardiotrophin-1 potentiate the elevation of serum corticosterone and IL-6 levels induced by IL-1. Furthermore, the potentiation of IL-1–induced serum corticosterone levels is not a consequence of the increased serum IL-6 observed after IL-1 administration. Thus either endogenous IL-6 does not mediate IL-1–induced corticosterone increase, or its role may be fulfilled by other cytokines. This is very important in the understanding of the activation of the hypothalamic-pituitary-adrenal axis and that potentiation of acute phase protein synthesis may represent an important feedback regulatory mechanism of inflammation.[37]

Clinical Relevance

Increased levels in the circulation have been identified following gram-negative bacterial infection and inflammatory reactions. IL-6 is detected in the serum of patients or experimental animals undergoing bacterial sepsis. Studies have indicated that IL-6 protects against virulent infection and suggest that the protective effect may be at least partially mediated through neutrophils.[1,111,436] IL-6 in these conditions is one of the more easily measured cytokines in the blood. Also, LPS responsiveness of proinflammatory cytokines (IL-1β, IL-6, IL-8, and TNFα) in whole blood from people with high and low levels of high-density lipoproteins is different, presumably of importance in inflammation and atherogenesis.[151] By secretion of pro-inflammatory cytokines, mast cells assist in the recruitment of monocytes and T lymphocytes into the vascular tissue, thereby promoting monocyte and/or macrophage-derived, cholesteryl-containing ester foam cell formation. Mast cells facilitate foam cell formation by promoting native and oxidized low-density lipoproptein (Ox-LDL) uptake by macrophages. Mast cell–derived cytokines and growth factors and tryptase might activate proliferation of vascular smooth muscle and fibroblasts, allowing the development of the obstructive lesions observed in human atherosclerosis.[270]

Balanced production of cytokines by alveolar macrophages may be very important for inflammatory outcome. During acute complications of lung transplantation, it has been shown that alveolar Ms display an early activation with oversecretion of IL-6, which is involved in tissue injury, counterbalanced by a late activation in which TGFβ predominates, mediating tissue repair.[337]

IL-6, produced by macrophages in the periprosthetic membranes surrounding joint replacements, has been implicated as a causal agent in osteolysis and prosthetic loosening and, when produced by T cells from the femoral head of patients with rapidly destructive coxopathy, has also been related with this pathological condition.[51,516] Further studies suggest that secretion of IL-6 by osteoblasts is crucial for stimulation of bone resorption not only by parathyroid hormone, but also by parathyroid hormone–related protein, vasoactive intestinal peptide, and β-adrenergic agonists, such as isoproterenol.[199]

Because IL-6 is an autocrine growth factor for many types of cells, its hyperproduction has been associated with a variety of malignancies, including plasmacytoma, multiple myeloma, uterine cervical carcinoma, and Kaposi's sarcoma.[1,472] A consensus regarding myeloma cell growth factor responsiveness and the ability to produce autocrine IL-6 has not yet been obtained; however it is thought to be caused by the heterogeneity observed; between cell lines and in clinical disease.[574] A central role for STAT3 has been suggested in IL-6–induced regulation of growth and differentiation in M1 leukemia cells, which determines the cellular decision from cell growth to differentiation in M1 cells.[383]

Considering the role of IL-6 in inflammation and immune response, and its known association with increased levels of MyD116 and GADD 34 mRNAs (genes involved in the prevention of apoptotic death of cells), pathological effects of herpes simplex virus can result because of a combination of direct viropathic effects and immunological reactions to viral antigens, namely a selective activation of IL-6 expression.[251]

Reviews emphasize the presumed activities of IL-6 in normal skin; in some diseases with cutaneous involvement in the pathogenesis of both local and systemic inflammation, including surgical ones, tumor development, autoimmune diseases, infectious diseases, and others.*

Therapeutic Applications

IL-6 may be useful to support neutrophil and megakaryocyte growth in patients treated with high doses of chemotherapy. However, alterations in platelet function in patients receiving IL-6 as cytokine therapy have been reported.[398] In experimental conditions, IL-6 altered platelet function as measured by reactivity to thrombin, even though effective at promoting platelet production.[415] Also, patients infected with HTLV-1 have been reported to respond to IL-6.[485] IL-6 reduces myocardial damage in mice with viral myocarditis, probably through the modification of immune responses together with reduction in viral replication. However, early activation of immune responses and attenuation of viral replication appear most significant, as reflected in the limited time window during which IL-6 is effective in myocarditis.[252]

Strategies designed to interfere with either autocrine or paracrine growth-promoting effects of IL-6 in malignancies may be useful.[472]

INTERLEUKIN-7

Interleukin-7 (IL-7) is an interleukin produced by epithelial and mesangial stromal cells, which serves as a differentiation factor for B cells in the early stages of their development and also supports the growth of some thymocytes and T lymphocytes.[138]

Synonyms

IL-7 was formerly known as lymphopoietin 1 (LP-1), B-cell growth factor, and pre–B-cell growth factor.

General Characteristics

The three-dimensional structure of IL-7 is not known, but it is a member of the four α-helical short-chain cytokine family (152AA). It stimulates early B- and T-lymphocyte growth and the proliferation and differentiation of mature T cells, which are produced by stromal marrow and thymus cells.[71,421,432] IL-7 can be classified as a CSF.[152]

Other general characteristics of IL-7 include:

Molecular Weight

The literature values for the molecular weight of IL-7 vary from 20 to 28 kDa. The following molecular weights have been reported: 25 kDa (monomer),[1,152,341,389,421] 20 to 28 kDa,[71,436] and 22 to 28 kDa.[472]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-7 is 60%.[71] Cross-species reactivity also has been observed and verified.

Chromosomal Location

The chromosomal locations of IL-7 and its receptor are 8q12-13 (IL-7) and 5p13 (IL-7R).

Cellular Origin

IL-7 is produced by bone marrow and thymic stromal cells, T lymphocytes, spleen cells, epithelial cells, and fibroblasts (Figure 22-16).[71,177,421,432]

Control of Synthesis and Release

Stromal cells from a variety of lymphoid and nonlymphoid tissues constitutively produce low levels of IL-7. This production is not affected by the lectins and mitogens that normally influence the synthesis of other growth factors.[472]

*References 153, 163, 300, 305, 386, 406, 433, 518, 527.

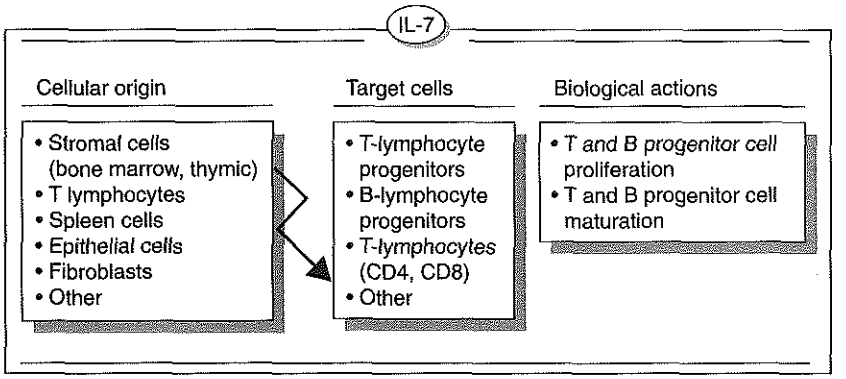

Figure 22-16 Cellular origin, principal target cells, and biological actions of IL-7.

Receptor (IL-7R)

The IR-7 receptor belongs to the hematopoietic receptor family, which includes the receptors for IL-2, IL-4, IL-6, IL-11, and GM-CSF.[341,472] It is a complex structure consisting of an IL-7 binding chain (α-chain, CD127) and the IL-2R γ-chain (γc). The CD127 contains the WSXWS motif, but it is unclear whether it should be included as a member of the cytokine receptor superfamily. The IL-7R γ-chain is a functional component enhancing IL-7 binding (shared with IL-4R, IL-9R, IL-13R, and IL-15R). This chain may explain the described high- and low-affinity binding sites. A soluble form of IL-7R has also been identified that originates by alternative splicing of the IL-7 gene.[71]

IL-7R is expressed on bone marrow lymphoid precursors, pro-B cells, thymocytes, mature T cells, and monocytes.[71,152] Data from a 1993 study suggest that heparin may act as a carrier for IL-7, blocking its interaction with target cells and protecting it from degradation during transit.[92]

Signal Transduction

IL-7 stimulates tyrosine phosphorylation of cellular proteins and tyrosine kinase–dependent activation of phosphatidylinositol-specific phospholipase C.[71] IL-7 has been observed to induce a rapid and dose-dependent tyrosine phosphorylation of JAK1 and JAK3 and concomitantly the tyrosine phosphorylation and DNA-binding activity of multiple STAT proteins. The STAT proteins used by IL-7 were identical to those induced by IL-2 and could be identified as various STAT5 isoforms. Moreover, the induction of both JAK1 and JAK3, and STAT5 activity strongly correlated with the growth-promoting effects of IL-7, suggests that this signal transduction mechanism may play a key role in IL-7–induced proliferation.[172]

Biological Actions

IL-7 promotes the growth of B- and T-cell progenitors (probably at the same level of development as IL-3 or GM-CSF) and proliferation of mature T cells (CD4 and CD8). It also facilitates the differentiation of both T-cell progenitors and Tc cells but not of B cells. It can stimulate T cells to proliferate even with a suboptimum concentration of IL-2.[1,71,341,436,485] IL-7 increases production of IL-2 and expression of IL-2R in T lymphocytes and stimulates the generation of LAK activity.[472] It also appears to promote TCR gene rearrangement among pre-T cells, namely D-J β rearrangement.[152,538] It induces secretion of IL-1α, IL-1β, IL-6, and TNFα by monocytes and tumoricidal activity in these cells.[341,485] IL-1 and TGFβ can block the stimulatory effects of IL-7.[472] IFNα and IFNβ have been found to be potent inhibitors of IL-7–induced growth of early B lineage cells and have no effect on cell growth induced by IL-2, IL-3, IL-4, or autogenous factors. The combination of IL-7 and these IFNs induces bcl-2 down regulation and cell death by apoptosis. This may explain this inhibition factor, which maintains the balanced production of normal B lineage cells.[562] Another demonstration of a selective induction of CD23 expression on activated human T cells cultured in the presence of IL-7 indicates that this cytokine has an important role in the regulatory network of the immune response.[75] IL-2 and IL-7 reciprocally induce IL-7 and IL-2 receptors on γδ T-cell intraepithelial lymphocytes with subsequent activation. The sources of these two cytokines were neighboring epithelial cells (IL-7) and αβ T cells (IL-2 and IL-7), respectively.[177] IL-7R is indispensable for normal lymphocyte development, and the IL-7R α chain not only causes progenitors to proliferate, but also has a distinct activity in inducing differentiation. Thus the signals that mediate a differentiative function of the IL-7R in B lymphopoiesis are specific and distinct from those causing proliferation.[97]

Clinical Relevance

IL-7 is known to regulate HIV-1 replication in naturally infected peripheral blood mononuclear cells (PBMCs).[488] From asymptomatic, chronically infected donors, IL-7–induced virus replication and increased proviral DNA levels in these cells are probably independent of the stimulation of IL-1β, IL-6, or TNFα production by PBMCs.

Therapeutic Applications

IL-7 may be useful in tumor therapy because of its ability to enhance the generation of Tc lymphocytes and LAK cells, even in the absence of IL-2.[341] Because of its capacity to stimulate lymphopoiesis, IL-7 may also be helpful for the therapy of some immunodeficiencies or to accelerate recovery following bone marrow transplantation.[472,485] IL-7 is also able to induce the proliferation of pro-B cells and CD4 and CD8 T cells and to enhance cytotoxicity of Tc and NK cells, indicating its possible therapeutic applications by enhancement of the immune system (tumors and infections). Its significant cross-species reactivity allows exogenous administration of human rIL-7, which protects mice against acute parasite challenge. This protection results from the stimulation of IFNγ production and augments the CD8 T-cell–mediated cytotoxic response.[260]

Interleukin-8

Interleukin-8 (IL-8) is a chemokine produced by monocytes, endothelial cells, and other cells that acts as a chemotactic and activator for neutrophils and may play a role in the extravasation of neutrophils in inflammation.[138] (For additional information, see later section on chemokines.)

Interleukin-9

Interleukin-9 (IL-9) is a cytokine produced by T cells and macrophages that acts as a growth factor for some T-cell populations and bone marrow–mast cell progenitors.[138]

Synonyms

IL-9 was formerly known as human p40, mouse IL-9 as p40, mast cell growth-enhancing activity, and T-cell growth factor III (TCGF-III).

General Characteristics

The three-dimensional structure of IL-9 is not known. However, it is known to be a glycoprotein of the four α-helical short-chain family (126AA). Similar to IL-2, it is a T-cell–derived T-lymphocyte growth factor with no effect on resting cells.

Other general characteristics of IL-9 include:

Molecular Weight

The literature values for the molecular weight of IL-9 vary from 14 to 40 kDa. The following molecular weights have been reported: 14 kDa,[341] 40 kDa,[421,485] 30 to 40 kDa,[1,152] 20 kDa,[436] and 32 to 39 kDa.[71,389,472]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-9 is 55%.[71] Mouse IL-9 has activity on human cells, but human IL-9 is inactive on mouse cells.

Chromosomal Location

The chromosomal location of IL-9 is 5q23-31, 5q31.1(IL-9).[71] The chromosomal location of its receptor is unknown.

Cellular Origin

IL-9 is produced by some activated T cells (mainly by activated CD4 Th2 lymphocytes for which it represents an autocrine growth factor) and Hodgkin's lymphoma cells (Figure 22-17).[71,341]

Control of Synthesis and Release

The mechanisms for controlling the synthesis and release of IL-9 are currently unknown.

Receptor (IL-9R)

This is a single-chain receptor, which is a heavily glycosylated protein of 64 kDa, associated with the IL-2R γ-chain. Both membrane-bound and soluble forms of the IL-9R exist. It is expressed on T helper clones, macrophages, some T-cell tumors, and mast cell lines.[71,341]

Signal Transduction

IL-9 causes tyrosine phosphorylation of proteins but not of MAP kinase.[71] It has also been demonstrated that JAK1 was constitutively associated with the IL-9 receptor. Activated STAT complexes induced by IL-9 have been found to contain STAT1, STAT3, and STAT5 transcription factors. Moreover, sequence homologies between human IL-9R tyrosine 116 and tyrosines of other receptors activating STAT3 and STAT5 have been observed. Collectively, these data indicate that a single tyrosine of the IL-9 receptor required for activation of three different STAT proteins is necessary for distinct activities of this cytokine, including proliferative responses.[125]

Biological Actions

IL-9 is a T-cell growth factor that acts in synergy with other cytokines (with IL-2, it causes proliferation of T cells and with IL-4, it promotes IgE and IgG synthesis by plasmacytes).[341] However, it supports the growth of some Th2 T-cell clones in the absence of IL-2 or IL-4. It has also been found to enhance the proliferative action of IL-3 on mast cell progenitors, to augment basophil proliferation and erythroid colony formation, and to stimulate the proliferation of megakaryoblastic leukemia cells.[71,432,485]

Clinical Relevance

IL-9 can support cell proliferation in the absence of an antigen or APC. Overproduction of it may lead to T-cell tumors, particularly of Th2 lymphocytes. In certain lymphomas, such as Hodgkin's lymphoma, it may act as an autocrine signal for cellular proliferation.[341,472] IL-9 may play a role in the development of acute myeloblastic leukemia by stimulating leukemic cells to enter the S-phase rather than preventing cell death. In addition, IL-9 acts synergistically with stem cell factor for recruiting quiescent leukemic cells in the cell cycle.[312]

IL-9 is a member of the Th2 cytokine family and has been implicated as an essential factor in determining mucosal immunity and susceptibility to atopic asthma. It has also been found in association with severe asthma and to cause airway hyperresponsiveness.[29,57,597]

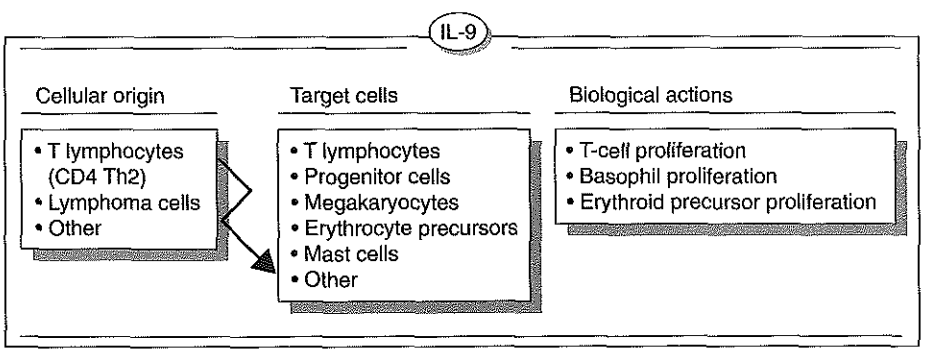

Figure 22-17 Cellular origin, principal target cells, and biological actions of IL-9.

Therapeutic Applications

Currently, there are no therapeutic applications of IL-9.

INTERLEUKIN-10

Interleukin-10 (IL-10) is a cytokine produced by activated macrophages, certain lymphocytes, and other cells that decreases both innate and T-cell–mediated immune inflammation; it inhibits the production of cytokines by activated T cells, plays a role in B-cell activation, inhibits production of IFNγ, and blocks antigen presentation and macrophage formation of IL-1, IL-6, and TNF.[138]

Synonyms

IL-10 was formerly known as B-cell–derived T-cell growth factor, cytokine synthesis inhibitory factor (CSIF), MCGF, and thymocyte growth-promoting factor.*

General Characteristics

IL-10 is a member of the four α-helical cytokine family and probably functions as a homodimer (160AA).[1] However, its three-dimensional structure is not yet known. It is a pleiotropic Th2 CD4 lymphocyte cytokine (also Th1 in humans) with the capacity to inhibit cell-mediated responses but also to enhance some specific aspects of the immune reaction. This gives it unique immunoregulatory properties.

This cytokine has been shown to have a 70% identity with an open reading frame (BCRF1) of the Epstein-Barr virus (EBV) genome. It and the protein encoded by BCRF1 (vIL-10) have some common activities, such as suppression of IFN production and macrophage activation.[71] This homology raises the possibility that EBV has captured and processed the human gene as a means of inhibiting antiviral immunity. EBV infection can cause immune suppression, which is probably dependent on an IL-10–like viral peptide.[472] vIL-10 shares with IL-10 predominantly inhibitory effects, such as macrophage deactivation conducing to a local immunosuppressive effect, which is particularly important in tumor biology and treatment.[43]

Other general characteristics of IL-10 include:

Molecular Weight

The literature values for the molecular weight of IL-10 vary from 17 to 40 kDa. The following molecular weights have been reported: 17 to 21 kDa,[341,389] 18 to 20 kDa,[1] 40 kDa,[421] 18 kDa,[152,436,472] and 35 to 40 kDa.[71]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-10 is 72%.[71] Human IL-10 is active on mouse cells, but murine IL-10 is inactive on human cells.

Chromosomal Location

The chromosomal locations of IL-10 and its receptor are 1 (IL-10) and 11 (IL-10R).

Cellular Origin

IL-10 is produced by Th0 and Th2 subsets of CD4 T lymphocytes (Figure 22-18). Data suggest that IL-10 can also be produced by activated B cells, some Th1 cells, CD8 T cells, activated macrophages, and other cells, such as eosinophils, dendritic cells, and keratinocytes.[1,71,152,341,383]

Control of Synthesis and Release

IL-10 production is enhanced in human T cells by IL-12 and IL-6 and in monocytes by TNFα. These findings suggest that IL-10 production by human T cells and monocytes is differentially regulated. IL-10 inhibits the production of IL-6, IL-12, and TNFα, which may indicate a potential mechanism of negative feedback regulation of the immune response.[110,499] IL-12 induces differentiation of Th1 cells, primarily through its ability to prime T cells for high IFNγ production, which in turn is an inhibitor of IL-10 production. Besides the presence of IL-12 during the first several days of in vitro clonal expansion of polyclonally stimulated human

*The same name is more consistently attributed to IL-3 and IL-4 (MCGF-II).

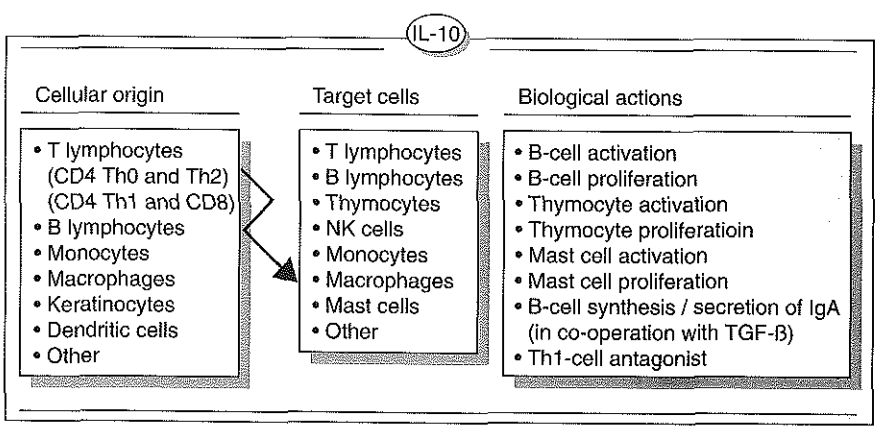

Figure 22-18 Cellular origin, principal target cells, and biological actions of IL-10.

peripheral blood, CD4 and CD8 T cells induce stable priming for high IL-10 production, but IL-4 almost completely suppresses this priming for IL-10 production.[185] Recombinant IFNβ blocks proliferation but enhances IL-10 secretion by activated human T cells.[435] Activation of human monocytes by LPS results in an initial burst of inflammatory cytokines, such as TNFα, that is followed by the secretion of anti-inflammatory mediators, such as IL-10. The regulation of IL-10 expression is more complex than that of TNFα.[358] Vasoactive intestinal peptide (VIP), a neuropeptide present in the peptidergic innervation of lymphoid organs and expressed in thymocytes and peripheral lymphocytes, has the capacity to modulate cytokine expression in T lymphocytes. VIP and the structurally related neuropeptide PACAP-38 inhibit IL-10 production by spleen cells or thymocytes.[348] Proopiomelanocortin peptides may be able to up regulate the production of IL-10 in monocytes and thereby contribute to immunosuppression.[46] Triggering of the CD23 molecule at the surface of human macrophages induces the generation of IL-10 through a cAMP-dependent mechanism. Concomitantly, this generation of IL-10 is down regulated by NO. This generation is also produced after triggering of the CD23 antigen. Collectively, these data indicate that human macrophages produce IL-10 after triggering of the CD23 molecule and that this production can regulate the inflammatory state of these cells.[148]

Receptor (IL-10R)

IL-10R is a single-chain receptor. IL-10R belongs to the class II cytokine receptor family that also includes the IFN receptors (IFNγ and IFNαβ receptors). The extracellular region consists of two homologous fibronectin type III domains that are without the WSXWS motif characteristic of class I cytokine receptors. It is expressed on B cells, thymocytes, and other cellular lines such as mast cells and macrophages. Human IL-10R mRNA is restricted mostly to hematopoietic cells and cell lines.[71]

Signal Transduction

Signal transduction by IL-10 is still unknown but likely to involve the JAK family of kinases.[71] The signal transduction cascades initiated by IL-10 ligation to its cognate receptor seem to rapidly and transiently stimulate phosphatidylinositol 3-kinase activity associated with the p85 subunit of the enzyme. IL-10 also activates p70 S6 kinase that is inhibited by the immunosuppressive drug rapamycin.[104]

Receptors for IL-10 and IL-6 cytokines appear to use similar signaling mechanisms for inducing transcription through IL-6 response elements. The cytoplasmic domain of the IL-10R contains two motifs that have been identified in the signal-transducing receptor subunits for IL-6 and known to be required for activating STAT3 and inducing transcription through IL-6–responsive elements. To determine whether the IL-10R has signaling functions similar to IL-6R in cells normally expressing these receptors, leukocytes of the B-, T-, and NK-cell lineages have been treated with either cytokine. Data demonstrate that the IL-10R, unlike other members of the IFN receptor family, is highly effective in recruiting the signaling pathways of IL-6 type of cytokine receptors.[301]

Biological Actions

IL-10 causes the inhibition of general proinflammatory cytokine synthesis, APC function, and cell-mediated immunity and induces the terminal differentiation of B cells into plasmacytes, which results in production of antibodies. Consequently, it has important effects on T and B lymphocytes, NK cells, monocytes and/or macrophages, and mast cells.[341,436] It is characterized by a paradoxical duality of function (negative and/or positive; Box 22-5).

This cytokine is a pleiotropic cytokine that can suppress cytokine expression by NK cells and Th1 lymphocytes, thus down regulating cell-mediated immunity and stimulating humoral responses.[596] Resulting T-cell anergy may then play an important role in the induction and maintenance of antigen-specific T-cell tolerance.[201] IL-10 is also capable of down regulating the release of IL-6 and PGE2. Endogenously synthesized IL-10 limits the immune complex–induced secretion of proinflammatory cytokines TNFα and IL-1β.[41] The antiinflammatory properties of IL-4, IL-10, IL-13, and TGFβ are associated with their ability to repress the production of proinflammatory cytokines and to favor the release of interleukin I receptor anatagonist (IIRA). Inhibition by IL-10 of proinflammatory cytokine release (IL-2 and IFNγ by Th1 cells) appears to occur at the level of gene

BOX 22-5 Duality of IL-10 Function

Negative Actions

- Inhibition of cytokine synthesis by activated Th1 and NK cells (indirect effect, mediated by a primary action on macrophages [Ms])
- Inhibition of cytokine secretion (IL-1, TNFα, IL-12, chemokines, GM-CSF, and G-CSF) by mononuclear cells
- Inhibition of IFNγ-induced production of reactive oxygen radicals and NO by macrophages
- Down regulation of MHC class II expression and of co-stimulators, such as B7, on Ms (inhibition of the accessory functions of Ms in T-cell activation)
- Antiimmunoinflammatory activity caused by down regulation of Th1 T cells, Ms, and NK cells

Positive Actions

- Chemoattractant for diverse cell types
- Synergizes with IL-2 and IL-7 in the proliferation of thymocytes and T cells
- Synergizes with other cytokines to stimulate proliferation of B cells, thymocytes, and MCs
- Stimulates B lymphocytes (together with TGFβ, causes IgA production, induces B-cell proliferation, and may be a switching factor for the production of IgG4)

transcription for TNFα and both transcriptionally and post-transcriptionally for IL-1β.[315] However, IL-10 is unable to induce IL1-RA by itself or to amplify the LPS-induced production by PMNs. It is able to increase its release when TNFα is the triggering signal.[345] The action of IL-10 as a potent inhibitor of TNFα expression and release from alveolar macrophages and peripheral blood monocytes may have an important role in the cytokine network of local immune response similar to its pulmonary one.[13] Despite IL-1α and TNFα release by alveolar macrophages, IL-6 release can only be suppressed to some extent by a combination of IL-4 and IL-10 (inhibiting the transcription rate of the IL-6 gene).[132,599] It has been suggested that the down regulation of fibrinogen biosynthesis by IL-4, IL-10, and IL-13 represents a protective vascular effect.[551]

Alternately, it is known that IL-10 has both stimulatory and inhibitory effects on diverse types of cells, including co-stimulation of T-cell proliferation (particularly Th2 cells), chemoattraction of CD8 T cells, and stimulation of LAK cell activity.[43] Also, osteoclast-like cells demonstrated an up regulation of NO production and inducible NO synthase mRNA by IL-8 and IL-10.[504]

Clinical Relevance

IL-10 has not been implicated in virus-induced diseases, but the mimicry of IL-10 by EBV is a method for pathogens to interfere with host defense mechanisms. This interference can have possible important pathological consequences.[472] IL-10, in addition to down regulating the cellular immune response to HIV-1, may also play a role in TNFα-mediated activation of HIV-1 replication.[164] During the acute phase of Kawasaki disease, levels of IL-10 are markedly elevated. This increase in serum IL-10 levels may contribute to the up regulation of humoral immunity and to the down regulation of acute inflammation.[275] An imbalance of Th-cell populations leads to the secretion of mostly IL-4 and IL-10 at the start of infection. The concomitant down regulation of IFNγ secretion reversed the host's resistance to *Trypanosoma cruzi*.[27] IL-10 has been shown to exert an inhibitory effect on cell-mediated immunity with a contribution to parasite Ag-induced T-cell hyporesponsiveness observed in patients with chronic *Schistosoma haematobium* infection.[276] It has also been demonstrated that diminished IL-10 production in asthma permits the unopposed synthesis of proinflammatory cytokines, thereby contributing to the development and severity of asthma.[60] Increased IL-10 serum levels in patients with solid tumors may have important implications for future investigations, immunological monitoring, and therapeutic intervention on neoplastic patients and suggests a mechanism for tumor cells escaping from immune surveillance.[168]

Polymorphisms in cytokine genes can influence immune responses, inflammation, and tissue injury and may affect the outcome of hematopoietic stem cell transplantation. Among recipients of hematopoietic cells from an HLA-identical sibling, the IL-10-592A allele seems to be a marker of a favorable outcome after transplantation. Despite advances in supportive care, severe grade III or IV graft-versus-host disease (GVHD) remains a serious complication of transplantation and contributes to transplantation-related mortality. High level of IL-10 production by recipients' cells during the early posttransplantation period mitigates the intensity of the alloimmune response and GVHD-induced inflammation, thereby reducing the clinical manifestations of GVHD and associated mortality. Knowledge of the IL-10 promoter-region genotypes, and possibly of polymorphisms in other immune regulatory genes, could be incorporated into the pretransplantation risk-assessment process and serve as a guide for the planning of treatment. The use of alternative approaches, such as nonablative conditioning regimens, might reduce morbidity and mortality in selected high-risk patients. Further insight into the mechanism underlying the association between the IL-10 promoter-region genotype and GVHD could prompt new strategies for modulating the intensity of the alloimmune response and reducing the toxicity of GVHD.[322]

Therapeutic Applications

Being a modulator of cytotoxic cell activity (macrophages, NK cells, and Th1 cells), IL-10 may be able to ameliorate clinical situations characterized by a hyperinflammatory reaction, such as septic shock. Its capacity to inhibit the production of IFNγ (namely by Th1 cells) is also of interest in various clinical situations, particularly those in which it is important to suppress delayed types of hypersensitivity responses (DTHR) without affecting antibody production.

IL-10 is also an efficient inhibitor of tumor metastasis in experimental models in vivo at doses that do not have toxic effects on normal cells. Histological characterization after IL-10 treatment has confirmed the absence of CD8 and CD4 T cells and macrophages at the sites of tumor growth; however, abundant NK cells were localized at these sites.[596] Human IL-10 differs from its EBV homologue viral IL-10 (vIL-10), because it can stimulate the acquisition of an effective, specific, and long-lived antitumor immune response in murine models and can reverse the local immunosuppressive effects of vIL-10. This indicates a potential role for IL-10 administration in the biological therapy of cancer and suggests a broader interpretation of IL-10 biology.[43]

Interleukin-11

Interleukin-11 (IL-11) is a cytokine produced by bone marrow stromal cells that stimulates megakaryocyte proliferation and B-cell differentiation.[138]

Synonym

IL-11 was formerly known as adipogenesis inhibitory factor.

General Characteristics

IL-11 belongs to the four α-helical long-chain cytokine family (179AA). Information is incomplete about its three-dimensional structure. It is known to be a bone marrow

stromal cell–derived cytokine involved in lymphopoiesis and hematopoiesis.[71,485]

Other general characteristics of IL-11 include:

Molecular Weight

The literature values for the molecular weight of IL-11 vary from 19 to 23 kDa. The following molecular weights have been reported: 20 kDa,[1,152] 23 kDa,[71,421,436] and 19 to 21 kDa.[389]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-11Rα is 84%.[71,384] Human IL-11 is active on mouse cells.

Chromosomal Location

The chromosomal locations of IL-11 and its receptor are 19q13.3-13.4 (IL-11) and 9p13 (IL-11Rα-chain).

Cellular Origin

IL-11 is produced by bone marrow stromal cells, trophoblast cells, glial cells, and IL-1–stimulated fibroblasts (Figure 22-19).[1,71,152,377]

Control of Synthesis and Release

Synthesis of IL-11 is induced by IL-1 and TGFβ in stromal cells and fibroblasts; cytokines that inhibit its production remain to be defined. In addition, IFNα has been found to down regulate IL-1–induced IL-11 in human bone marrow stromal cultures.[7]

Receptor (IL-11R)

The high-affinity receptor for IL-11 is composed of two subunits, IL-11 receptor α-chain (IL-11Rα) and gp130, the common subunit of the IL-6, CNTF, LIF, and OSM receptors. The IL-11 receptor-specific α chain shares homologies with the α chain of the CNTF and IL-6 receptors, confirming evolutionary conservation at the level of gene organization among the hematopoietic cytokine receptor family.[85]

The IL-11Rα has the requirement of either the human or mouse gp130 molecule for signaling because the human IL-11Rα-chain is able to form a functional receptor complex in association with murine gp130 or human gp130. This complex results in high-affinity IL-11–binding sites and IL-11–dependent cellular proliferation.[384] The functional receptor complexes assembled in response to IL-6, IL-11, LIF, OSM, and CNTF all involve the signal transducer gp130. IL-6 and IL-11 induce homodimerization of gp130, and LIF, OSM, and CNTF heterodimerize gp130 with other gp130-related β subunits. IL-6, IL-11, and CNTF also require a specificity-determining α-subunit not directly involved in signaling. Studies have established that stromal and/or osteoblastic cells are targets for the actions of all the members of the cytokine subfamily that share the gp130 signal transducer; this suggests that different receptor repertoires may be expressed at different stages of differentiation of this lineage.[36]

Signal Transduction

IL-11 intracellular signaling travels through cytoplasmic kinases of the Janus family. How JAKs accomplish the multiple functions of IL-11 has not been determined and only a few associated downstream proteins have been identified, in particular the evidence for the IL-11–induced association of protein phosphatase (PP2A), P13K, and Yes to JAK2. This novel finding of JAK2 and/or PP2A binding and release may have relevance to many serine and/or threonine-regulated mechanisms, such as P13K, STAT, and mitogen-activated protein kinase (MAPK) activation. These associations support a model of JAK2 as a protein kinase docking protein of IL-11 signal transduction, which may be applicable to other gp130 and JAK signal transduction systems.[176] IL-11R can also serve as a substitute IL-6R in activating gene expression in target cells that are devoid of the appropriate ligand-binding receptor subunits.[33]

Biological Actions

The biological activities of IL-11 are not fully characterized, but they are similar to those of IL-6, LIF, and OSM.[485] For example, IL-11 (1) stimulates the development of diverse hematopoietic cell lineages from bone marrow precursors (especially of early hematopoiesis), including monocytes and/or macrophages and megakaryocytes; (2) is a growth factor for plasmacytes, hematopoietic multipotential cells,

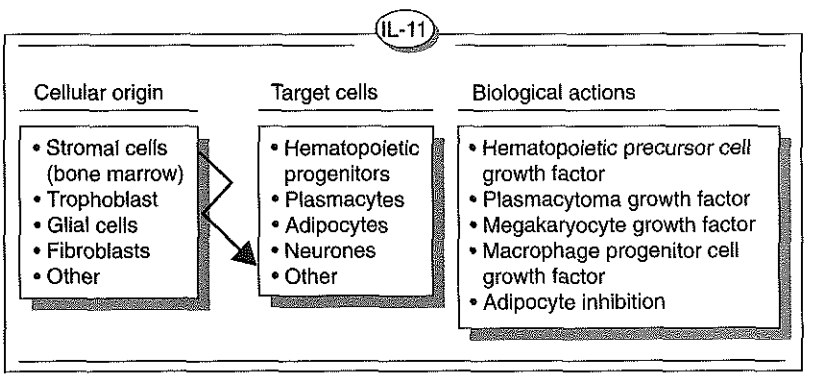

Figure 22-19 Cellular origin, principal target cells, and biological actions of IL-11.

and committed megakaryocytic and macrophage progenitor cells; and (3) inhibits adipogenesis in mouse preadipocytes. It is also involved in the production of APP and has been reported to increase the number of antibody-forming B cells in response to an antigen.[7,71,485] However, when compared with IL-6, IL-11 and LIF induced only minimal stimulation on production of APP by human primary hepatocytes. Thus circulating levels of IL-11 or LIF do not contribute significantly to the production of APR in vivo, and they do not seem to account for the difference in APR response between systemic lupus erythematosus and other inflammatory rheumatic diseases.[181] It has been shown that IL-6, IL-11, and to a lesser extent LIF in rat hepatocytes are potential mediators of metallothionein synthesis in inflammation.[102]

Cerebral expression of IL-11 by glial cells is important because IL-11 has been shown to have effects on neuronal electrophysiology, has overlapping functions with the neuroactive cytokine IL-6, and is part of the gp130-associated neuropoietic family of cytokines.[377]

Clinical Relevance

IL-11 is expressed in leukemic myeloid cells, and their proliferation is regulated by this cytokine, which acts synergistically.[311]

Therapeutic Applications

As a stimulator of megakaryopoiesis, IL-12 may be of therapeutic benefit in patients with platelet deficiencies.[1] Ex vivo expansion with stem cell factor and IL-11 augments both short-term recovery posttransplant and the ability to transplant bone marrow serially.[219]

INTERLEUKIN-12

Interleukin-12 (IL-12) is a heterodimeric cytokine produced by phagocytic cells, B cells, and other antigen-presenting types of cells. It is a potent inducer of cytokine production, causes T and NK cells to secrete IFN-γ, is a growth factor for preactivated T and NK cells, and enhances cytotoxic activity in $CD8^+$ T cells and NK cells. It also has a role in the generation of T helper type 1 cells and in the differentiation of cytotoxic T lymphocytes.[138]

Synonyms

IL-12 was formerly known as cytotoxic lymphocyte maturation factor (CLMF), natural killer cell stimulatory factor (NKSF), and T-cell stimulatory factor.

General Characteristics

Information is incomplete concerning the three-dimensional structure of IL-12. However, it is known to be a heterodimeric four α-helical short-chain cytokine (196AA/306AA) that stimulates T- and NK-cell function.[71,341,421] It consists of two covalently linked polypeptide chains, one of 35 kDa (p35, IL-12α) and the other of 40 kDa (p40, IL-12β). The p35 chain has a four α-helix structure, similar to that of many other cytokines, but the p40 chain of IL-12 is homologous to the IL-6R, containing an Ig domain and a WSXWS motif. Thus, IL-12 appears to be composed of one cytokine-like polypeptide and one receptor-like polypeptide.[1]

Other general characteristics of IL-12 include:

Molecular Weight

Depending on its molecular form, the literature values for the molecular weight of IL-12 vary from 24 to 70 kDa. The following molecular weights have been reported: 24 to 33 kDa (p35) and 34 to 44 kDa (p40),[341] 70 kDa,[1,152,421] 35 (p35) and 40 (p40) kDa,[389,421] and 30 to 33 kDa (p35) and 35 to 44 kDa (p40).[71]

Cross-Reactivity

The cross-reactivities (amino acid sequence homology between human and mouse) for molecular forms of IL-12 include IL-12 p35 (60%) and IL-12 p40 (70%).[71] Human IL-12 is inactive on mouse cells, and murine IL-12 is active on human cells.

Chromosomal Location

The chromosomal locations of the molecular forms of IL-12 are 3p12-3q13.2 (IL-12α) and 5q31-33 (IL-12β).

Cellular Origin

The p35 subunit of IL-12 is produced by T and B cells, NK cells, neutrophils, monocytes, and macrophages (at least in the mouse). The p40 subunit is produced mainly by B lymphocytes, activated monocytes, and dendritic cells (including epidermal Langerhans' cells). Consequently the principal sources of IL-12 are B cells and monocytes and/or macrophages (Figure 22-20).* In the brain, microglia-like cells are the primary producers of the p40 transcripts. In contrast, the IL-12 p35 gene is constitutively expressed in the brain at a very low level.[409]

IL-12 is the only cytokine acting as a regulator of the effector phase of cell-mediated immune reactions that is not produced by T cells. However, the IL-12 receptor is restrictedly expressed by T lymphocytes and NK cells.

Control of Synthesis and Release

It has been suggested that IL-12 is up regulated as part of the early cytokine response of mononuclear phagocytes to infectious agents and that the cellular events associated with phagocytosis are themselves a potent signal for IL-12 production. IL-12 released by infected macrophages can further up regulate pathogen-specific CD4 T-cell effector function.[179] IL-12 expression is regulated by NO, which may exert an autoregulatory and paracrine control of IL-12 gene expression.[448] IL-10 inhibits the production of IL-6, IL-12, and TNFα, probably indicating a potential mechanism of negative feedback regulation of the immune response, as

*References 152, 216, 253, 341, 448, 536, 590.

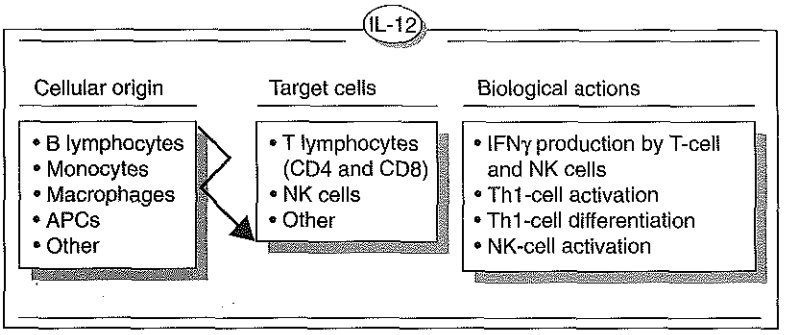

Figure 22-20 Cellular origin, principal target cells, and biological actions of IL-12.

IL-12 or IL-6 can induce the expression of IL-10 by PHA-stimulated T cells.[110] The gp120 glycoprotein of HIV is an inducer of IL-12 expression in monocytes and/or macrophages, and IFNγ is an essential cofactor for IL-12 secretion, especially in differentiated macrophages.[159] The production of IL-12 is stimulated by bacteria, bacterial products, and intracellular parasites and enhanced by priming with GM-CSF and IFNγ. It is inhibited by IL-10.[536] Bioactive IL-12 (p70) is composed of the two subunits (p35, which is only secreted as part of the p70 dimer, and p40, which can also be secreted by itself). The two subunits are encoded by separate genes, and to what extent the expression of each of the subunits contributes to the regulation of IL-12 production is being investigated. Results indicate that in LPS-stimulated whole blood and purified monocytes, p70 and p40 production are enhanced by IFNγ and inhibited by IL-10 and IL-4. However, IFNγ and IL-10 had stronger effects on p70 production than on p40 production, and IL-4 affected p40 production more strongly. Concomitantly, in all experimental conditions tested, p40 production greatly exceeded p70 production, suggesting that p35 expression was limiting. Analysis of p35 and p40 mRNA expression by polymerase chain reaction (PCR) confirmed this belief. Resting purified monocytes expressed neither p40 nor p35 mRNA. The effects of IFNγ, IL-10, and IL-4 on the p35 mRNA expression in LPS-stimulated purified monocytes were similar to the effects of these cytokines on p70 protein production, and the p40 mRNA expression corresponded to p40 protein production. These results imply that production of the two IL-12 subunits is differently regulated for each subunit, mainly at the level of mRNA expression, and that the level of bioactive IL-12 production in monocytes in response to LPS and cytokines is determined by the level of p35 expression.[489] IFNγ, which is up regulated during infection, acted in synergy with other stimuli on IL-12 synthesis, suggesting an amplification loop for IL-12 production, whereas IL-4, IL-10, IL-13, and TGFβ were inhibitory. The existence of a broad range of stimuli from a wide variety of pathogenic organisms underscores the fundamental importance of IL-12 in host defense.[487]

Receptor (IL-12R)

IL-12R is a single-chain receptor expressed only on T cells and NK cells (structurally similar to the G-CSF receptor). One component of the IL-12 receptor complex shows it to be related to gp130.[71] To date, a large number of receptors for IL-12 have been found but only on PBMC following activation with PHA or IL-2. Studies have found that the expression of IL-12R on a human γδ T-cell line responds to IL-12 with enhanced cytolytic activity and increased expression of cytolytic effector molecules granzyme B and perforin.[281]

Signal Transduction

STAT4 has been found to be essential for mediating responses to IL-12 in T lymphocytes and NK cells and regulating the differentiation of both Th1 and Th2 cells.[256,525] IL-12 activates STAT4, STAT1α, and STAT3, and induces complexes containing STAT4 only, STAT4 with STAT1α, STAT3 with STAT1α, or STAT1α only in preactivated primary NK cells. STAT1α activation by IL-12 is correlated with increased phosphorylation of serine but not tyrosine. IL-2 induced tyrosine phosphorylation of JAK1 and JAK3, with IL-12 inducing phosphorylation of JAK2 and TYK2 in both preactivated primary NK and NK3.3 cells. Differential phosphorylation and consequent differential activation of both separate and overlapping STAT proteins by IL-2, IL-12, and IFNα may provide a molecular basis for the similarities and differences in the actions of these cytokines on NK cells.[281,591]

Biological Actions

The major biological activity of IL-12 is on T and NK cells where it increases cytokine production, proliferation, and cytotoxicity. Its production occurs several hours after exposure to infectious agents, which induces a rapid production of IFNγ by NK and later by T cells. Thus IFNγ potentiates APC functions important in clearing infectious agents (phagocytosis, oxidative burst, and production of NO) and increases further production of IL-12. IL-12 has been clearly demonstrated to be important in the generation of CD4 and CD8 type of Th1 cells both in vivo and in vitro. IL-12 also primes naive T cells for concomitant high IFNγ and IL-10 production, whereas IL-4 is required for IL-4 priming, thus suggesting that these corresponding genes and possibly others are independently regulated. IL-12 is therefore involved in the skewing of cytokine production toward a type 1 T response. It is now becoming clear that IL-12 acts as both a proinflammatory cytokine and an immunomodu-

lator and therefore bridges the innate and antigen-specific adaptive immune responses to intracellular bacterial, fungal, and protozoan pathogens.[185,536,579]

IL-12 has been called "the jump starter of cell-mediated immunity," indicating that IL-12 acts early in infection as a switch driving CD4 T cells (with IFNγ) to a cellular Th1 response.[152]

It is likely that IL-12 plays a pivotal role in the host defense against intracellular pathogens.[183] For example, it (1) promotes cell-mediated immunity by polarizing Th types of cytokine responses (causing DTHR), (2) enhances the lytic activity of NK and/or LAK cells, (3) augments specific Tc responses, (4) induces the production of IFNγ, and (5) suppresses the development of Th2 types of cytokine responses and humoral immunity, particularly IgGl and IgE responses. Thus IL-12 selectively promotes differentiation of Th1 lymphocytes and potentiates cell-mediated immunity while suppressing Th2-dependent functions, such as the production of IL-4, IL-10, and IgE antibodies.

Studies have documented that the immunoregulatory functions of IL-12 may play a role in promoting endogenous protective responses during infections or contribute to pathological conditions resulting from unregulated cytokine expression. Pathogen induction of IL-12 elicits IFNγ production by NK cells, contributing to early defense during certain bacterial, parasitic, and viral infections. IL-12 also facilitates the development of Th1 lymphocytes required for late protection against bacteria, parasites, and fungi. During viral infections, however, there appear to be mechanisms independent of IL-12 for inducing protective T-cell responses. In contrast, negative regulation of IL-12 during acute infections can be a key event in the establishment of chronic infection and protection against harmful excessive cellular immune response.[50]

IL-12 is a multifunctional cytokine capable of inhibiting neovascularization.[473] Because the human IFNγ-inducible protein 10 (IP-10) can also inhibit neovascularization, IP-10—induced by IL-12 through the intermediate cytokine IFNγ—was tested to determine if it might be a mediator of IL-12 angiogenesis inhibition. Murine IL-12–induced murine IP-10 expression in mouse splenocytes and human IFNγ-induced human IP-10 expression in purified human endothelial cells suggest that IL-12 can induce IP-10 expression in certain cells. These results document the important role of IP-10 as a mediator of angiogenesis inhibition by IL-12 and raise the possibility that IP-10 may also contribute to the antitumor effect of IL-12.[485]

Cytotoxic activity of both NK cells and Tc lymphocytes is enhanced by IL-12 (it acts synergistically with IL-2 to induce IFNγ synthesis by these cells and is considered as the most potent NK-cell stimulator known). This cytotoxic enhancement occurs in parallel with depression of IgE production and reduction of IL-4 secretion (IL-12 and IL-4 cross regulate one another's activities). IL-12 effects are only seen early, whereas IL-4 effects are maintained. Studies have suggested a molecular basis for these temporal differences of IL-12 and IL-4 on Th1 and Th2 responses.[341,541] These differences are dependent on the specific characteristics of T-cell receptor functions: on Th1 lymphocytes, the IL-4R and the IL-12R remain expressed and functional, whereas on Th2 lymphocytes, IL-12R functional defects were identified following commitment to the Th2 lineage.

CD40-CD40L interaction synergizes with IL-12 in selectively enhancing IFNγ production by T cells. Both CD4 and CD8 T cells were able to produce IFNγ in the presence of helper signals from IL-12 and CD40, although CD8 T cells were less active. CD40-CD40L interaction also up regulates IL-12 production.[416] CD8 Tc lymphocytes are important mediators for resistance to infections and malignant diseases, and IL-12 function in the generation of important human antiviral CD8 T-cell responses also has been demonstrated by augmented IFNγ production during Tc generation.[45]

It has been suggested that CD4 human thymocytes have the potential to develop into cells producing the Th2 cytokines IL-4 and IL-5, whereas the ability to produce both Th1 cytokines and IL-10 is acquired only after priming with IL-12.[364] In the absence of APC, IL-12 and TNFα both demonstrate an inhibitory effect on the proliferation of CD8 Tc lymphocyte clones, whereas IL-10 enhances the proliferation. IL-12–induced inhibition of CD8 Tc clones is not mediated by the endogenous production of TNFα by these clones. The strong inhibitory effect of IL-12 and TNFα does not result in apoptosis, and these cytokines do not alter the cytotoxicity of CD8 Tc clones. When CD4 T-cell clones were tested in the absence of APC, no substantial change in IL-2–dependent proliferation caused by IL-10, IL-12, and TNFα could be measured. Because these effects on established Tc clones are in contrast to the effects of IL-10, IL-12, and TNFα during the induction phase of immune responses, a dichotomy of immunomodulatory cytokines, such as IL-10, IL-12, and TNFα, early and late in the immune response has been suggested.[547]

Clinical Relevance

IL-12 may be a marker of Th1-mediated pathological conditions, such as autoimmune type 1 diabetes mellitus.[341] Th1 cells are critically involved in several pathological conditions, such as contact hypersensitivity, and it has been suggested that IL-12 may play a dominant role in vivo in the induction of this pathology.[438] The relative increase in IL-12 mRNA in chronic atopic dermatitis skin lesions suggests a possible role for IL-12 producing cells in modulating chronic inflammation.[207] The verification that higher mRNA expression of the regulated IL-12 p40 subunit, but not IL-10, was present in sarcoid lung cells, with elevated levels of p40 protein found in sarcoid bronchoalveolar lavage fluid, and that sarcoid alveolar macrophages produce greater amounts of IL-12 than normal alveolar macrophages favors the hypothesis that sarcoidosis is a Th1-mediated pathological condition driven by chronic, dysregulated production of IL-12 at sites of disease.[367]

Defective IL-12 production is associated with increased susceptibility to infection (e.g., familial disseminated *Mycobacterium avium* complex infection, *T. cruzi* infection, and human visceral leishmaniasis), a finding that supports the critical role of this cytokine in host defense and in the regulation of the cellular immune response.[23,175,230] The loss of immune function following infection with HIV may result from altered production of immunoregulatory cytokines, such as IL-10 and IL-12. It was suggested that monocytes from HIV-positive individuals secrete decreased amounts of IL-12, which may lead to the development of Th2 type of responses characterized by high IL-10 secretion and immune dysfunction.[109,110]

As previously discussed, IL-12 is considered to be a key factor for the induction of IFNγ, a cytokine essential for the lethal effects of endotoxin. Administration of a lethal or sublethal dose of live *Escherichia coli* to baboons results in the release of the nonfunctional subunit of IL-12, p40, and biologically active heterodimeric IL-12, p70. This finding is contrary to what might be expected if IFNγ were solely induced by IL-12. Lethally challenged baboons generated threefold more IFNγ at 6 hours than those receiving a sublethal dose. Moreover, higher levels of IFNγ were associated with lower p40 to p70 ratios, suggesting that in agreement with observations, in vitro IFNγ may have preferentially up regulated the release of p70 over p40. These data show that IL-12 is released in experimental septic shock in nonhuman primates and suggest that IL-10 and IFNγ are involved in the regulation of this release. Furthermore, this study indicates that the systemic release of IL-12 might be essential, but is not likely sufficient, to promote lethal production of IFNγ in sepsis.[243] IL-12 and PGE2 are two opposite immunomodulators: IL-12 enhances IFNγ production by activated CD4 T cells, whereas PGE2 inhibits the secretion of this cytokine. The relative contributions of these factors shift in time owing to different production kinetics, from a dominant IL-12 effect to a mixed IL-12/PGE2 effect; this may be largely determinant to T-cell activation and therefore lead to immunological dysfunction.[217]

IL-12 is also a critical cytokine regulating NK and T-cell function, and it has been suggested that reduced expression and production of IL-12 from activated umbilical cord blood may contribute to the immaturity in its cellular immunity and may explain decreased GVHD following umbilical cord blood stem-cell transplantation.[308]

Therapeutic Applications

IL-12 has been shown to exert striking therapeutic effects at nontoxic doses in mouse tumor models and in mouse models of a variety of infectious diseases and airway inflammation. In mouse tumor models, the therapeutic effects of IL-12 have been shown to result from its immunoenhancing activity, which requires both T cells and IFNγ. In some models, administration of IL-12 can result in antiangiogenic effects, which may also contribute to its antitumor activity. Tumor cell–induced angiogenesis is an essential requirement for the growth of solid neoplasms. The mechanism of antitumor action of IL-12 may depend not only on the immunostimulatory activity of this cytokine, but also on its effect on tumor cell–induced angiogenesis (IFNγ being a mediator of the antiangiogenic effect of IL-12).

IL-12 should be considered a potential candidate for the treatment of angiogenesis-dependent malignancies. Enhanced antitumor effects may be achieved by administering IL-12 in combination with certain other cytokines or with radiotherapy or chemotherapy. Additionally, IL-12 has been shown to be more efficacious than IL-2 in several murine tumor models, and toxicology studies suggest that it may have a substantially better therapeutic index. Also, the long serum half-life of IL-12 relative to other cytokines will allow more flexibility in dosing schedules. The striking therapeutic effects of IL-12 in these preclinical models have led to the initiation of clinical trials to evaluate the potential therapeutic activity of IL-12 in human cancer patients and in patients with HIV infection or with chronic hepatitis B or C virus infections.[183,184,339] Despite considerable advancement in anticancer therapy, minimal residual disease is still a major problem in the clinical management of cancer, including lymphoma. Experimental studies suggest that cytokines, such as IL-12, may have the potential to mediate antitumor effects against residual lymphoma without compromising lymphohematopoietic recovery.[552] IL-12 promotes specific and long-lasting antitumor immunity mediated by T cells in a variety of murine tumor models. It also synergizes with B7.1, a co-stimulatory molecule involved in the activation of T lymphocytes (CD80) to induce proliferation and cytokine production by both human and murine T cells in vitro. These activities support the potential clinical utility of combined gene therapy using IL-12 and B7.1-engineered autologous cells (tumor or fibroblasts) as a vaccine to elicit specific antitumor immunity.[600] IL-12 in combination with IL-2 enhanced the autologous antimelanoma Tc lymphocyte response, whereas B7.1 antigen expression on tumor cells did not increase antimelanoma Tc generation. This method represents a novel strategy to enhance the efficacy of recombinant anticancer vaccines and could be used to design more appropriate genetically modified tumor vaccines.[121,429]

Because of its multiple effects on immunoinflammatory response, recombinant IL-12 has been shown to have therapeutic activity in a variety of mouse tumor and infectious disease models and is being evaluated in clinical trials in human cancer patients. IL-12 also appears to play a role in the genesis of some forms of immunopathology, including endotoxin-induced shock and some autoimmune diseases associated with aberrant Th1 activity. Therefore IL-12 antagonists may also have therapeutic potential in the treatment of autoimmune disorders. In addition, intraocular injection of IL-12 significantly inhibited the development of endotoxin-induced intraocular inflammation, suggesting that IL-

12 can have an immunoregulatory function in some forms of inflammatory disease.[577]

IL-12 may also be potentially useful for adoptive immunotherapy, especially in immunosuppressed patients (caused by cancer or HIV infection) with decreased NK function and T-cell cytotoxicity.[1,341,472] Under appropriate conditions, IL-12 has therapeutic efficacy for promoting defense against a variety of pathogens and for use as a vaccine adjuvant to enhance beneficial Th1 over detrimental Th2 lymphocyte responses and provides new tools for the development of treatment and adjuvant strategies to potentiate beneficial or inhibit detrimental endogenous immune responses.[50]

INTERLEUKIN-13

Interleukin-13 (IL-13) is a cytokine produced by activated T lymphocytes that has structural and functional similarities to IL-4; it inhibits inflammatory cytokine production by LPS in human peripheral blood monocytes and may be involved in promoting B-cell division.[138]

Synonyms

IL-13 has been formerly known as NC30 (human complementary DNA [cDNA]) and P600 (mouse cDNA clone).

General Characteristics

IL-13 belongs to the four α-helical short-chain cytokine family (112AA). The structural homology between IL-13 and IL-4 and the juxtaposition of their encoding genes on chromosome 5 are probably related to a process of gene duplication. It is a highly pleiotropic cytokine produced by Th2 cells (such as IL-4), inhibiting macrophage responses.[71,341]

Other general characteristics of IL-13 include:

Molecular Weight

Depending on the degree of glycosylation, the literature values for the molecular weight of IL-13 vary from 9 to 17 kDa. The following molecular weights have been reported: 9 to 17 kDa,[341] 12 kDa,[335] 10 kDa,[389,436] and 12.4 kDa,[152] 9 kDa, and 17 kDa (glycosylated form).[71]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-13 is 58%.[71] There is a significant cross-species reactivity. Human and mouse IL-13 have no known activity on mouse B cells.

Chromosomal Location

The chromosomal location of IL-13 is 5q23-31.

Cellular Origin

Previously, IL-13 was considered to be predominantly produced by activated T cells, namely Th2 CD4 lymphocytes. Now it is known that CD4 T-cell clones belonging to Th0, Th1-like, and Th2-like subsets produce IL-13 following antigen-specific or polyclonal activation (Figure 22-21). In addition, EBV-transformed B-cell lines express IL-13 mRNA and produce small amounts of IL-13 protein.[120] IL-13 is also known to be produced by activated human CD4 and CD8 CD45R0 memory T cells and CD4 and CD8 CD45RA naive T cells. Collectively, it appears that IL-13 is also produced by peripheral blood T cells that also produce IL-4, but not IFNγ, and by naive CD45RA T cells. These observations, together with the long-lasting production of IL-13, suggest that IL-13 may have IL-4–like functions in situations in which T-cell–derived IL-4 is still absent or its production has already been down regulated.[248,548]

The production of IL-13 by basophils has been demonstrated to be localized in basophilic granules. Kinetic studies have demonstrated detectable IL-13 release at 3 hours, which steadily increased up to 24 hours. This is significantly different from the kinetics of basophil histamine and IL-4 release and suggests that basophils, in addition to secreting mediators, can represent an important source of proallergic cytokines.[318] Actual findings point to the fact that bone marrow–derived mucosal-like mast cells constitutively expressed IL-13, whereas bone marrow–derived connective tissue–like mast cells demonstrated IL-13 transcription only after Fcε activation or the addition of exogenous IL-3. A similar pattern of expression of IL-10 by these mast cells was also evident and matches that of IL-4 previously reported, suggesting that mucosal mast cells may have a constitutive

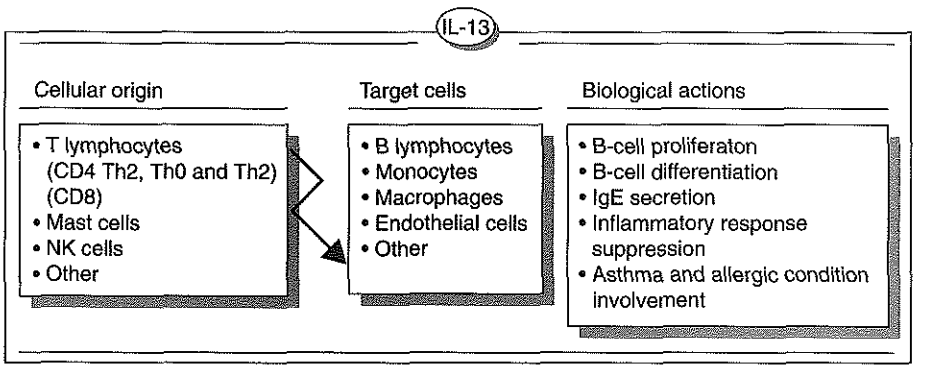

Figure 22-21 Cellular origin, principal target cells, and biological actions of IL-13.

repertoire of Th2 cytokines with potential antiinflammatory activity. Connective tissue MCs may not be this repetitive. However, production of such cytokines can be induced in the connective tissue mast cells and other cell types of the immune response by the addition of IL-3.[346]

Control of Synthesis and Release

Expression of IL-13 mRNA and production of IL-13 protein by peripheral blood T cells and T-cell clones are rapidly induced and are relatively long lasting, whereas IL-4 production by these cells is transient. In addition, IL-13 mRNA expression is induced by modes of activation that failed to induce IL-4 mRNA expression.[120] Because the primed T cells involved in IL-4 and IL-13 production contain higher levels of nuclear factor–activated T cells, preformed (NFATp), capable of binding to P elements of the IL-4 and IL-13 promoters, than do freshly isolated T cells, the NFAT-binding P elements are attractive candidates to mediate the coordinate expression of these two cytokine genes.[135] IL-13 production in all types of cells is enhanced by cyclosporin A. In contrast to IL-13, IL-4 production requires co-stimulation through CD3 and was inhibited by cyclosporin A. The unusual regulation and relative abundance of IL-13 make it an important candidate to be controlled tightly by dose and type of TCR ligands. Cyclosporin A is used widely to inhibit T-cell function, and the finding that IL-13 production is enhanced instead of diminished in the presence of *cyclosporin A may explain the Th2-inducing effects of this* immunosuppressor in vivo.[548]

Receptor (IL-13R)

The IL-13 receptor may share a subunit with IL-4R but not in the ligand-binding component. IL-13 lacks the T-cell–activating properties of IL-4 that are related to the fact that T cells fail to bind radiolabeled IL-13 and do not express the IL-13–specific receptor component.[120] The overlapping activities of IL-13 and IL-4 are probably due to the existence of common receptor components. Two proteins have been described as constituents of the *IL-4R (a high-affinity* IL-4 binding chain (p140, α-chain, CD124) and the IL-2R γ-chain also known as the common γ-chain (γc), but neither of these proteins binds IL-13. The IL-13 binding protein (IL-13R) has two consensus patterns characteristic of the hematopoietic cytokine receptor family and a short cytoplasmic tail. It shows homology with the IL-5 receptor, and to a lesser extent with the prolactin receptor.[74] The receptor for IL-4 and IL-13 was described as a shared heteromultimeric complex in which the common γc subunit was essential for activity. Endothelial cells bind both cytokines with high affinity, and it has been demonstrated that they express IL-4Rα but do not express the γc of the IL-2R. Therefore it is probable that the subunit structure of the functional receptors for IL-4 and IL-13 on human endothelial cells do not use or require the common γc of the IL-2R.[465]

IL-13R is expressed on endothelial cells and probably on the same cells expressing IL-4R or IL-5R.

Signal Transduction

IL-13 shares many biological activities with IL-4 and may share a common component required for signal transduction.[120] Compared with IL-4, IL-13 induces a similar alteration of the cytokine cascade and arachidonic acid metabolism, supporting the hypothesis that the two cytokines use a common receptor complex or signal pathway.[124] IL-13 activates STAT6 in B cells but not JAK3. This leads to the conclusion that γc is essential for activation of JAK3 and STAT6 in the signal transduction pathway of IL-4 in human B cells and that IL-13 does not use γc but activates STAT6 through an alternative pathway that is not impaired in B cells of XSCID patients.[237] However, IL-4 and IL-13 differentially regulate epithelial chloride secretion, which indicates that although postreceptor signaling events induced by IL-13 and IL-4 may be similar, endpoint function is cytokine specific.[560,603]

Biological Actions

IL-13 is a regulator of B cells and monocyte activity. On B cells, IL-13 functions as a co-stimulatory signal (together with a B-cell receptor or CD40), increasing B-cell proliferation and CD23 expression. In the presence of IL-13, interaction between CD40 and CD40L induces isotype switching to IgE synthesis (as occurs with IL-4). IL-13 can also inhibit monocyte and/or macrophage responses, suppressing the production of IL-1α, IL-1β, IL-6, IL-8, and TNFα (this action is shared by IL-4 and IL-10). IL-13 synergizes with IL-2 on NK cells to produce IFNγ. IL-13 has also been shown to prolong survival of human monocytes and increase surface expression of MHC class II and CD23.[71,341] IL-13 is a cytokine secreted by activated T lymphocytes and shares some, but not all, of its biological activities with IL-4. This includes inhibition of monocyte and macrophage activation, stimulation of human B cells, and induction of growth and differentiation of mouse bone marrow cells in vitro.[74,303]

IL-13 lacks the T-cell–activating properties of IL-4, *relying instead on differences in expression* and biological activities of these two cytokines on T cells with possible consequences for their relative roles in the immune system response.[120] IL-13 is described as a cytokine with Th2-like actions.[207] IL-13 and IL-4 exert similar, nonadditive effects on endothelial cells, inducing VCAM-1 expression and subsequent transmigration of eosinophils.[465] Experimental data indicate that exogenous rIL-13 induces extramedullary hematopoiesis in mice and suggest that endogenous IL-13 may contribute to replenishment of effector cells during strong Th2 responses.[303] IL-13 has also been found to induce *the expression and release of the IL-1 decoy receptor (type* II) in human neutrophils along with the production of the IL-1RA. Human rIL-13 induces cellular morphological changes in neutrophils that are typical of activated cells, increases tyrosine phosphorylation of several neutrophil proteins, and induces the synthesis of several neutrophil proteins but has no significant effect on phagocytosis and

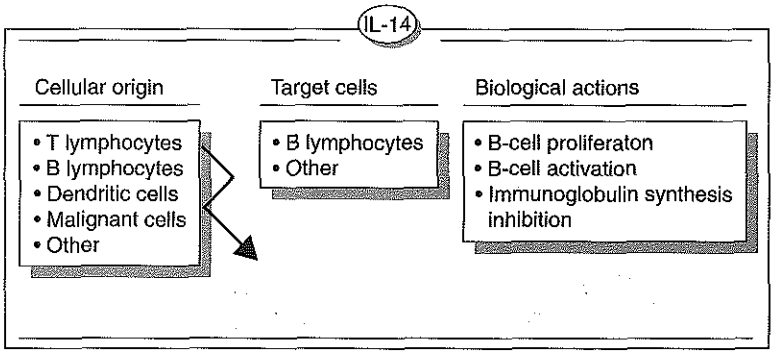

Figure 22-22 Cellular origin, principal target cells, and biological actions of IL-14.

apoptosis. Collectively, these results demonstrate that IL-13 is a modulator of several human neutrophil functions.[189] For example, IL-13 has been identified as a powerful regulatory tool for the inhibition of NO synthesis in human cells, which may be pathophysiologically relevant in NO-related inflammatory processes.[460] IL-13 suppresses the bone-resorbing activity stimulated by IL-1α by suppressing cyclooxygenase-dependent PG synthesis in osteoblasts.[400]

Clinical Relevance

Laboratory data have shown that acute atopic dermatitis skin lesions are associated with an increased expression of IL-13 mRNA.[207] IL-4 and IL-13 down regulate both the increase of fibrinogen secretion induced by IL-6 and fibrinogen mRNA levels, probably protecting vessel walls from monocyte injuries leading to atherosclerosis.[551] IL-13 may also exhibit a negative regulatory effect on neoplastic B cells in contrast with that observed in normal B cells and could be an important factor in the pathogenesis of chronic lymphocytic leukemia by preventing the death of monoclonal B cells.[83] IL-13 gene expression has been detected in the epithelial compartment of the nasal mucosa of 18 of 19 perennial allergic rhinitis patients but was undetected in normal volunteers and chronic infectious rhinitis patients, pointing to its intervention in local allergic reactions.[413]

Therapeutic Applications

IL-13 may have a role as an inhibitor of monocyte inflammatory cytokines (for example, induced by LPS) and thus may be useful as a therapeutic agent in septic shock. The peripheral blood of allergic individuals contains long-lived allergen-specific B cells that have already switched to IgE production and that are not sensitive to IL-4 and IL-13 treatment. This information may have implications for attempts to use cytokines or cytokine antagonists in therapy of type I allergy.[133]

Interleukin-14

Interleukin-14 (IL-14) is a cytokine produced by T lymphocytes and malignant B lymphocytes; it induces B-cell proliferation and inhibits Ig secretion.[138]

Synonym

IL-14 was formerly known as high molecular weight B-cell growth factor (HMW-BCGF).

General Characteristics

IL-14 is unrelated to any other cytokines but shares homology with complement factor Bb.[71] It is a B-cell growth factor produced by T cells (483AA).

Other general characteristics of IL-14 include:

Molecular Weight

The literature values for the molecular weight of IL-14 vary from 50 to 60 kDa. The following molecular weights have been reported: 50 to 60 kDa,[341] 53 kDa,[152,436] and 60 kDa.[71]

Cross-Reactivity

There are no reports of cross-activity of murine IL-14.

Chromosomal Location

The chromosomal location of IL-14 is unknown.

Cellular Origin

IL-14 is produced by activated T, B, follicular dendritic, and malignant cells (Figure 22-22).[71,152,341]

Control of Synthesis and Release

Mechanisms for controlling the synthesis and release of IL-14 are currently unknown.

Receptor (IL-14R)

A single type of receptor was detected on B cells; IL-14 causes up regulation of its receptor on these cells. IL-14R also binds complement fragment Bb.[71]

Signal Transduction

IL-14 causes increases in intracellular cAMP, DAG, and calcium.[71]

Biological Actions

IL-14 enhances the proliferation of activated B cells and may play a role in the development of B-cell memory. The

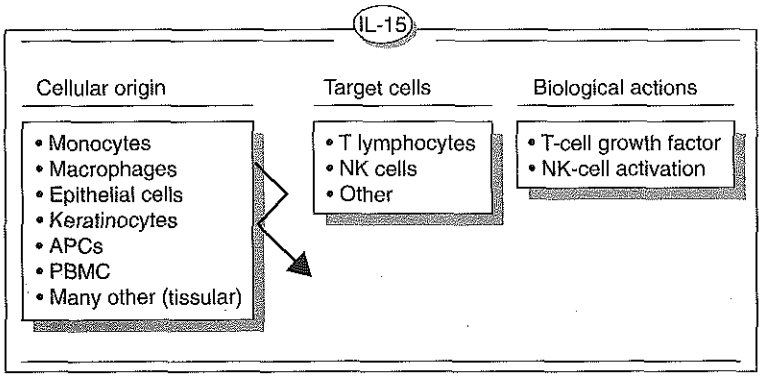

Figure 22-23 Cellular origin, principal target cells, and biological actions of IL-15.

presence of IL-14 in germinal center T cells and follicular dendritic cells suggests that during a secondary immune response, naive B cells migrating through the lymph node encounter antigen, become activated, express IL-14R, and consequently bind IL-14. This results in increased bcl-2 expression, which prevents apoptosis and permits B-cell memory development.[341] Despite the proliferative action on B cells, inhibition of Ig secretion is produced by IL-14.[71,152,341,432] IL-14, like IL-13 and TGFβ, is considered to be a down regulatory cytokine.[131]

Clinical Relevance

Hyperproduction of IL-14 together with IL-6 and IL-10 has been reported in patients with systemic lupus erythematosus.[341]

Therapeutic Applications

In a variety of malignant conditions, lymphoma or leukemia cells are able to proliferate with an IL-14 stimulus, implicating this cytokine in their expansion and survival. IL-14 down regulation or inhibition may also prove useful.[341]

INTERLEUKIN-15

Interleukin-15 (IL-15) is a cytokine released by mononuclear phagocytes and some tissue cells in response to events triggering innate immunity, such as viral infection; its primary function appears to be promotion of NK-cell proliferation.[197]

General Characteristics

The three-dimensional structure of IL-15 is a four α-helical bundle similar to IL-2 (four α-helical short-chain cytokine, 114AA). IL-15 has biological characteristics similar to those of IL-2, acting mainly on the proliferation of T cells. The discovery of IL-15 may explain the perplexing observation that IL-2–deficient mice have surprisingly conserved immune responses.[71,152]

Other general characteristics of IL-15 include:

Molecular Weight

The literature values for the molecular weight of IL-15 vary from 14 to 15 kDa. The following molecular weights have been reported: 14 to 15 kDa,[71,341] 12.9 kDa,[436] and 14 kDa.[152]

Cross-Reactivity

Human IL-15 is active on murine T cells.

Chromosomal Location

The chromosomal location of IL-15 is unknown. The chromosomal location of IL-15 is 4q31.

Cellular Origin

IL-15 is produced by multiple cellular and tissue sources (blood mononuclear cells, placenta, skeletal muscle, kidney, lung, liver, heart, bone marrow stromal cells, keratinocytes, Langerhans' cells, and other tissue-specific dendritic cells) and particularly by epithelial cells and monocytes (Figure 22-23).[53,71,152,373]

Control of Synthesis and Release

Optimal induction of IL-15 in murine macrophages requires both priming (IFNγ) and triggering (LPS, mycobacteria, or *Toxoplasma gondii*) stimuli. When compared with IL-12 mRNA synthesis by the same macrophages, IL-15 mRNA production was more resistant to inhibition by the down regulatory cytokines IL-14, IL-13, and TGFβ. Moreover, IL-10, which is inhibitory for most other monokines, increased levels of the IL-15 mRNA found after stimulation. Thus IL-15 is a product of the macrophage-monocyte lineage that is up regulated on activation. IL-15 could thus play an important role in the initiation of immune responses by microbial agents.[131] Ultraviolet B radiation (UVB) up regulates the expression of IL-15 in human skin, suggesting a new mechanism by which UVB can promote Ag-independent T-cell responses via elaboration of IL-15.[366]

Receptor (IL-15R)

IL-2R β- and γ-chains are both required for binding IL-15 and for signal transduction; the α-chain is not required.[71,152,191] Like IL-2, IL-15 causes the release of sIL-2Rα from PHA-activated human PBMCs in a concentration and time-dependent manner. This effect of IL-15 is largely direct and independent of IL-2. Blocking of the IL-2Rβ-chain prevents the release of sIL-2Rα by IL-15 but not by IL-2. IL-7, another cytokine using the γ-chain of the IL-2R, drives the release of sIL-2Rα as well. Several clinical condi-

tions are associated with abnormal serum sIL-2Rα levels and are monitored by the measurement of sIL-2Rα. The reason for sIL-2Rα release is not fully understood. In one study, IL-15, like IL-2, was shown to be a potent inducer of sIL-2Rα release in vitro.[534] Comparing the interactions of IL-2 and IL-15 with the IL-2Rβ and IL-2Rγ-chain subunits, it has been suggested that the existence of a human IL-15Rα subunit and physical evidence of this molecule has been obtained.[191] This indicates that IL-15 creates a less stable bridge between the IL-2Rβ and IL-2Rγ-chains than does IL-2.[318] IL-2 and IL-15 share many biological activities as a consequence of their use of the β- and γ-chains of the IL-2R. However, each cytokine binds to a specific receptor α-chain: IL-2 with low affinity and IL-15 with high affinity. IL-15, like IL-2, is also thought to up regulate expression of IL-2Rα on human T and B cells, but rapidly down regulate IL-15 high-affinity binding sites that represent IL-15Rα. This leads to a decreased responsiveness to IL-15 as measured by induction of JAK3 tyrosine phosphorylation. These results suggest a mechanism by which IL-15 may cooperate with IL-2 at the initiation of an immune response and enhance subsequent IL-2 responsiveness during T-cell expansion.[292] A murine IL-15–specific α-subunit has been identified, cloned, and shown to be structurally related to IL-2Rα. However, the murine IL-15Rα alone binds IL-15 with a 1000-fold higher affinity than that seen with IL-2Rα and IL-2. These studies have been extended into the human system with the isolation of three differentially spliced human IL-15Rα variants that are all capable of high-affinity binding of IL-15. The cytoplasmic domain of IL-15Rα, like that of IL-2Rα, is dispensable for mitogenic signaling, suggesting that the primary role of the α-chains is to confer high-affinity binding. At high concentrations, IL-15, like IL-2, is able to signal through a complex of IL-2Rβ and γ in the absence of the α subunit. The distribution and expression of the IL-15Rα are much wider than those of the IL-2Rα, suggesting a broader range of cellular targets for IL-15.[10]

Biological Actions

IL-15 has been shown to stimulate T-lymphocyte proliferation (especially Tc cells) and to facilitate their generation.[392] The similarity of IL-15 to IL-2 is also evident from its ability to enhance LAK activity and from the inhibition of IL-15 responses by anti–IL-2Rβ-chain antibody.[341] However, IL-15 has only some IL-2 functions, perhaps dependent on differences between the two cytokine receptors (presence of a unique IL-15 binding protein associated with the IL-2Rβ subunit). Unlike IL-2, IL-15 is produced by monocytes and/or macrophages and not by lymphocytes.[53,341]

NK-cell proliferation could not be initiated with rIL-15 as the sole co-stimulatory cytokine. However, NK-cell proliferation was initiated with rIL-15. Either rIL-10 or rIL-12, cytokines also produced by monocytes and other APCs are implicated in innate immune responses. These results support the notion that NK-cell proliferation occurs at different phases of the immune response, with the particular cytokine milieu influencing the repertoire of NK-cell–secreted cytokines, and that IL-15 may be a physiologically relevant ligand for NK-cell differentiation in vivo.[373,564] IL-2 and IL-15 may have different functional properties during the in vitro differentiation of IL-4–producing cells. The role of IL-15 in priming for IFNγ is not as important as that of IL-2, leaving this cytokine as the preponderant controller of Th1 differentiation in physiological situations. Finally, IL-15 has been shown to increase proliferation of activated CD4 T-cell blasts but not of naive CD4 T cells. Moreover, cultures containing both IL-2 and IL-15 show greater proliferation than either cytokine alone, suggesting an additive effect between these cytokines.[469]

IL-15 promotes cytokine production by human Th cells by (1) inducing IL-5 synthesis; (2) having a role at the site of allergic inflammation; and (3) having a role in the recruitment and activation of eosinophils by inducing Th2 cytokine production by T cells.[371] IL-15 has other activities, including chemotactic properties and inducing uropod formation on T lymphoblasts to which ICAM-3 is redistributed, representing a potent T-lymphocyte chemoattractant. Other adhesion molecules, such as ICAM-1, ICAM-2, CD43, and CD44, are also redistributed to the uropod, although in a smaller proportion of the cells. The effect of IL-15 was dose dependent and specifically inhibited by a monoclonal antibody (mAb) against this cytokine. Blocking experiments with anti–IL-2Rβ-chain mAb showed an inhibitory effect on IL-15–mediated redistribution of ICAM-3, whereas no effect was observed in the presence of anti–IL-2Rα-chain mAb. The M16, N9 uropod induced by IL-15 is enriched in many different adhesion receptors and, being well exposed to the external milieu, is likely to modulate the adhesive properties of lymphocytes.[355,390] In addition, because IL-15 is produced by keratinocytes, Langerhans' cells, and other tissue-specific dendritic cells, it may be important in attracting and activating antigen-specific Th1 T cells.[53]

It has been suggested that IL-15 derived from infected macrophages may contribute to the early activation of γδ T cells during salmonellosis.

Clinical Relevance

IL-15 and IL-2 induce expression of cell-surface IL-2Rα (CD25) on freshly isolated human PBMCs in the absence of other exogenous stimuli. They also stimulate the release of sIL-2Rα. On stimulation with rIL-15, more than 80% of all NK cells express CD25, and more CD8 lymphocytes are positive for CD25 compared with stimulation by rIL-2. These results may be clinically relevant because several diseases are associated with high serum levels of sIL-2Rα, which may be due not only to IL-2 but also to IL-15 stimulation.[533] UVB-induced down regulation of keratinocyte IL-15 production may contribute to the relative state of immunosuppression induced by sun exposure.[53] Experimental findings demonstrate that IL-15 triggers the growth

of leukemic B cells through IL-2R system subunits, pointing to the role of this cytokine in regulating the neoplastic proliferation in chronic lymphoproliferative disorders.[535] Synovial fluids from RA patients were found to contain chemotactic activity, which was attributable in part to the presence of IL-15. Moreover, in a murine model, injection of rIL-15 was found to induce a local tissue inflammatory infiltrate consisting of mostly T lymphocytes. Synovial fluid T lymphocytes proliferate in response to IL-15, demonstrating that continued responsiveness to IL-15 is a feature of T cells after entry into the synovial compartment. These data suggest that IL-15 can recruit and activate T lymphocytes in the synovial membrane, thereby contributing to RA pathogenesis.[355] A defect in IL-15 signaling may contribute to the XSCID in humans, resulting from mutations in the receptor common γ-chain.[191]

Therapeutic Applications

IL-2 and IL-15, which uses the β- and γ-chains of the IL-2R, have been found in melanoma cells and anti–IL-15 mAbs to inhibit HLA class I expression in these cells. Therefore these cytokines may modify the behavior of both stromal and neoplastic cells inside a tumor. These data may have important implications for our understanding of tumor–host interactions and in future strategies of immunotherapy.[22] When compared with IL-2, which enhances both spontaneous and antigen-induced lymphocyte proliferative responses, IL-15 rarely increases spontaneous lymphocyte proliferation. Thus IL-15 may help to correct the impaired proliferative response of CD4 lymphocytes from HIV-1–infected persons without the mitogenic effect of IL-2, which also may induce HIV-1 expression.[411]

INTERLEUKIN-16

Interleukin 16 (IL-16) is a proinflammatory cytokine that is chemotactic for $CD4^+$ T lymphocytes, monocytes, and eosinophils.[78]

Synonym

IL-16 was formerly known as lymphocyte chemoattractant factor (LCF).

General Characteristics

IL-16 has a tetrameric structure that appears to be an absolute requirement for biological activity. The amino acid structure predicts six β-sheets, of which the β2-sheet contains a sequence probably important in the autoaggregation of monomers (130AA). The 15 hydrophilic C-terminal amino acids are thought to be important in IL-16 binding to its receptor. There is no direct evidence that the secreted molecule is glycosylated. A protein of 80 kDa has been identified on both human and murine lymphocytes using various antibodies directed against the 14-kDa secreted protein. Biological activity suggests that IL-16 is a proinflammatory and immunomodulatory cytokine.[79]

Other general characteristics of IL-16 include:

Molecular Weight

Depending on its molecular form, the literature values for the molecular weight of IL-16 vary from 14 to 80 kDa. The following molecular weights have been reported: 14 to 17 kDa, 56 kDa (homotetramer), and 80 kDa (precursor).[79]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-16 is more than 85%.[79] Murine IL-16 has chemoattractant bioactivity for human CD4 T cells, and this activity is inhibited by antihuman IL-16 mAb.[79]

Chromosomal Location

The chromosomal location of IL-16 is 15q26.1. No similarities to other cytokine genes have been found, and the chromosomal location is not proximal to that of any other cytokines.[79]

Cellular Origin

IL-16 synthesis has been demonstrated in CD8 lymphocytes (Figure 22-24).[336] CD4 and CD8 T cells constitutively express mRNA for IL-16; however, fully assembled bioactive tetrameric cytokine is preformed only in CD8 T cells. CD8 T cells contain constitutively synthesized and stored IL-16 in bioactive form. It is unclear whether IL-16 is synthesized

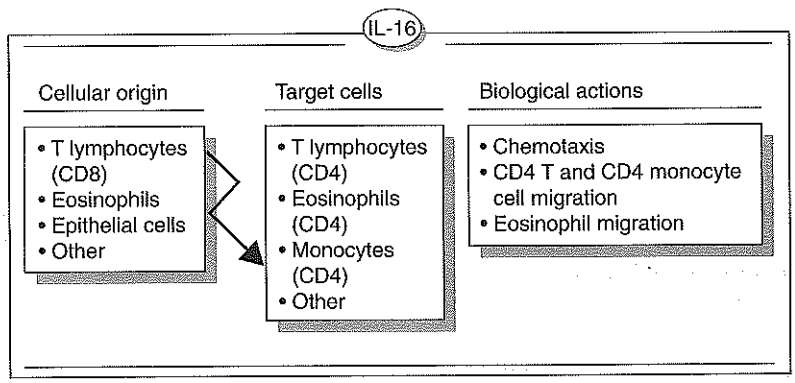

Figure 22-24 Cellular origin, principal target cells, and biological actions of IL-16.

and released from classic Tc or other CD8 T subsets, but the immunosuppressive effect is more consistent with a suppressive T-cell origin. CD4 T lymphocytes contain IL-16 mRNA and the 80-kDa precursor but no preformed bioactive cytokine. Following mitogen, antigen, or CD3 stimulation, CD4 T cells release bioactive IL-16. Eosinophils and airway epithelial cells are sources of bioactive IL-16, and brain, thymus, spleen, whole blood leukocytes, and pancreas express IL-16 mRNA.[79,321]

Control of Synthesis and Release

Serotonin induces secretion of IL-16 from CD8 but not from CD4 T cells. This induction does not require *de novo* protein synthesis. Serotonin, via serotonin type 2 receptors, may promote the recruitment of CD4 T lymphocytes into an inflammatory focus.[298] IL-16 is released in response to an antigen, mitogen, histamine, or serotonin. Histamine induces secretion of IL-16 by interaction with H2-type histamine receptors on CD8 cells, and serotonin induces secretion by interaction with S2-type receptors. The mechanism of IL-16 secretion is unknown; however, the intracellular 80-kDa molecule suggests the necessity of protein processing, resembling IL-1 (which also lacks leader sequences) that is secreted after processing and formation of pore complexes.[79]

Receptor (IL-16R)

The CD4 molecule is thought to be the IL-16 receptor[407] because it serves as a receptor for the secreted form of IL-16, and IL-16 binding to CD4 induces signal transduction, which affects the activation state of the cell.[336] The binding region on CD4 appears to be distant from the MHC and HIV-1 gp120 binding regions and related with the CDR3 region near the OKT4 binding domain. The use of CD4 as the receptor for IL-16 implies that CD4, in addition to being an accessory molecule in APC/T-cell binding, has functions as a chemoattractant and growth factor receptor. The tetramerization of CD4 seems to be indispensable for IL-16 binding (also in a tetrameric complex), whereas gp120 can bind to single CD4 molecules.[79]

Signal Transduction

The interaction between IL-16 and its receptor CD4 leads to an increase in intracytoplasmic calcium and inositol triphosphate. Recombinant IL-16 induces rapid translocation of PKC from the cytosol to the membrane in CD4 cells, including normal blood T cells, suggesting a role for PKC in CD4-mediated migratory responses.[408] The binding of IL-16 to CD4 results in activation of p56(lck), whose adaptor function is essential for the chemotactic response. Subsequently, increases in intracellular Ca^{2+} and phosphatidylinositol 1,4,5-triphosphate occur, as does translocation of PKC from cytosol to membrane.[105] IL-16 induces rises in intracellular Ca^{2+} and inositol triphosphate and autophosphorylation of p56lck. The transmission of a migratory signal is associated with the SH2- and SH3-mediated recruitment of other signaling molecules and not with lck kinase activity. The requirement for the SH2 and SH3 recruitment domains for other intracellular proteins suggests that they provide the link to the cytoskeleton for the motile response. Phosphoinositide 3-kinase, phospholipase Cγ, and PKC are also implicated in IL-16–induced motile response. There are similarities in the signal transduction pathways and cellular functions induced by IL-16 and HIV-1 gp120, although it is not known if IL-16 induces other biological activities that have been attributed to gp120, such as cytokine synthesis and arachidonate metabolism in monocytes.[79]

Biological Actions

The principal known action of IL-16 is its chemoattractant activity for CD4 lymphocytes and for CD4 eosinophils and monocytes.[79,321] The chemoattractant activity for activated and resting T cells is both chemokinetic and chemotactic. For eosinophils and monocytes, this is mostly a chemotactic activity. IL-16 is a competence growth factor for CD4 lymphocytes, inducing a G0 to G1 cell-cycle change but not cell division. IL-16 induces the expression of high-affinity IL-2R on these cells but not the synthesis of IL-2. IL-16 provides a functional role for the existence of CD4 receptor on non-T cells (besides chemoattraction, it increases adhesion of eosinophils to matrix proteins and induces IFNγ-independent HLA-DR expression on monocytes).[79,408] IL-16 is chemotactic for CD4 T cells and induces functional IL-2 receptors in CD4 T cells. The investigation of the potential regulatory effects of IL-16 on CD3/TCR-mediated lymphocyte activation indicates that this proinflammatory state is associated with subsequent transient inhibition of responsiveness via the CD3/TCR complex.[105] IL-16 is a natural CD4 ligand that suppresses T-cell proliferation in a dose-dependent manner. The unresponsiveness induced by rIL-16 is distinct from that of other CD4 ligands in that CD4 and IL-2R expression are unaffected. The failure of rIL-2 to restore proliferation suggests that the decrease in T-cell responsiveness induced by rIL-16 may result from an interruption in the IL-2R–signaling mechanism. These experiments may help explain how CD4 delivers both activating and inhibitory signals and provides a rationale for the role of IL-16 in the regulation of immune responses.[523] CD4 plays an important regulatory role in T-cell activation by switching from augmentation of antigen-specific responses in the presence of APCs, to antigen-independent inflammatory responses following dimerization by anti-CD4 antibodies or tetramerization by IL-16. This cytokine could contribute in part to a general recruitment of T cells during an inflammatory process and render the responsive lymphocytes temporarily less susceptible to antigen stimulation.

IL-16 has also been described as a suppressor of HIV infectivity, inhibiting HIV-1 replication in infected PBMCs. Pretreatment of CD4 lymphoid cells with rIL-16 repressed HIV-1 promoter activity up to sixtyfold. This effect of IL-16 requires sequences contained within the core enhancer but is not due simply to the down regulation of transcription

factors binding to this element.[79,336] In patients undergoing hepatic resection, both IL-6 and IL-16 are suggested to induce hepatic regeneration and the production of APP in the liver.[478] IL-16 produced by eosinophils could contribute to enhancing the recruitment of additional populations of CD4 lymphocytes and eosinophils into sites of allergic inflammation.[321]

Clinical Relevance

IL-16 is thought to play a role in allergic inflammation.[321] Accumulation of CD4-activated lymphocytes in the airways of asthmatics is generally attributed to the presence of chemoattractant cytokines, namely IL-16 and MIP1α.[106] Most studies have focused on asthma and granulomatous diseases because IL-16 represents about 80% of the CD4 lymphocyte chemoattractant activity found in bronchoalveolar lavage from patients with asthma. Mast cell histamine might induce the secretion of IL-16 after an allergenic challenge. In granulomatous inflammatory responses, the production of histamine and serotonin by mast cells induces the secretion of IL-16 and consequent intervention of CD4 T cells. IL-16 has been found in sarcoid granuloma and in granulomas of infective origin, particularly *Mycobacterium tuberculosis*.[79]

Therapeutic Applications

IL-16 inhibitors may prove useful in suppressing the proinflammatory effects of IL-16. The capacity of this cytokine to inhibit HIV infection and simultaneously prime CD4 lymphocytes for IL-2–induced proliferation suggests a complementary role in the treatment of HIV infection.[79]

INTERLEUKIN-17

Interleukin-17 (IL-17) is a prototype member of a new cytokine family secreted by activated $CD4^+$ and $CD8^+$ T lymphocytes. It is classified as proinflammatory cytokine, because it induces many mediators of inflammation that are involved in the proliferation, maturation, and chemotaxis of neutrophils.[581]

Synonyms

Two T-cell–derived molecules termed cytotoxic T lymphocyte-associated antigen 8 (CTLA 8) and herpesvirus saimiri gene 13 (HVS13) were proposed as novel cytokines that bind to a novel cytokine receptor named IL-17, vIL-17, and IL-17R, respectively.[587] Analysis of the cDNA-encoding murine IL-17 (cytotoxic T lymphocyte–associated antigen 8) predicted a secreted protein sharing 57% amino acid identity with the protein predicted from ORF13, an open reading frame of a T lymphotropic virus, HVS.[169]

General Characteristics

Human IL-17 has been described as a glycoprotein of 155 amino acids secreted as a homodimer by activated memory CD4 T cells.[169] Like IL-10 and BCRF1, IL-17 and ORF13 suggest a virus-captured gene with possible functional activity. Both glycosylated and nonglycosylated forms of the homodimeric IL-17 molecule are secreted yet are not related to the functional activity of this cytokine.[65]

Human IL-17

A cDNA encoding human IL-17 (hIL-17) has been cloned from a CD4 T-cell library.[588] The predicted 155–amino acid sequence contains an N-terminal signal peptide and exhibits 72% amino acid identity with HVS13 and 63% with murine CTLA-8. High levels of hIL-17 were induced from primary peripheral blood $CD4^+$ T cells on stimulation. When expressed in CV1/EBNA cells, recombinant hIL-17 was secreted in both glycosylated and nonglycosylated forms. An hIL-17 Fc fusion protein and supernatants from cells transfected with hIL-17 induced IL-6 and IL-8 production and enhanced the surface expression of the ICAM-1 in human fibroblasts.[588]

Mouse IL-17

Mouse IL-17 is a cytokine preferentially expressed by αβ TCR CD4neg CD8neg T cells. It represents a novel molecule, originally designated murine CTLA-8, and later described as a cDNA isolated from an activated T-cell hybridoma produced by fusing a mouse cytotoxic T-cell clone and a rat T lymphoma. This cDNA, which contains mRNA instability sequences characteristic of many cytokines, encodes a putative secreted protein that is homologous to the ORF13 gene of herpesvirus saimiri. The human homologue to this molecule has been identified as the proinflammatory cytokine IL-17. The cDNA encoding mouse IL-17 from a cDNA library, generated from αβ TCR CD4neg CD8neg thymocytes, shares 87.3% amino acid identity to the previously described murine CTLA-8. Comparison of murine CTLA-8 with the cDNA isolated from activated rat splenocytes revealed that murine CTLA-8 is the rat homologue of IL-17. Mouse IL-17 mRNA is specifically expressed by activated αβ TCR CD4neg CD8neg T cells, a small subset with a potentially important role in immune regulation. Mouse, rat, and human IL-17 can induce IL-6 secretion in mouse stromal cells, indicating that all homologues can recognize the mouse receptor.[272]

Other general characteristics of IL-17 include:

Cross-Reactivity

Human IL-17 cross-reacts with mouse cells.[272]

Chromosomal Location

The chromosomal location of IL-17 is 2q31.[65]

Cellular Origin

IL-17 is produced by activated memory CD4 T cells (Figure 22-25).[169] This represents a rather restricted set of T lymphocytes that contrasts with the ubiquitous expression of IL-17 receptor.[65]

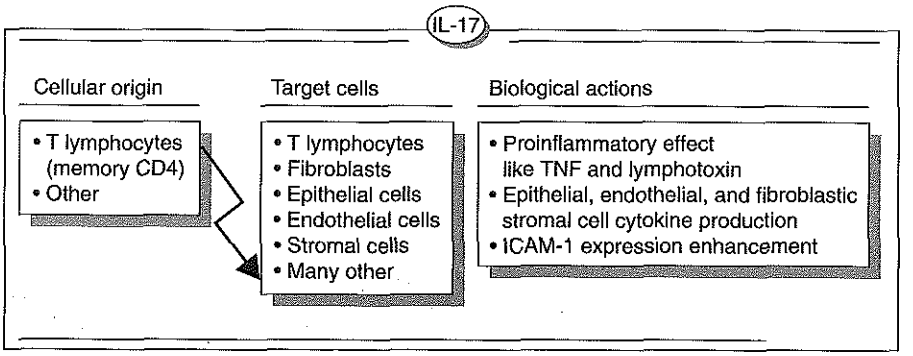

Figure 22-25 Cellular origin, principal target cells, and biological actions of IL-17.

Control of Synthesis and Release

Under normal conditions, the IL-17 gene is induced to synthesize cytokine from activated memory CD4 of T lymphocytes. Whether IL-17 itself has a role in IL-17 production and what kind of stimuli will be able to activate IL-17 synthesis remain to be elucidated.[65]

Receptor (IL-17R)

IL-17R is unrelated to previously identified cytokine receptor families. A recombinant soluble receptor inhibits T-cell proliferation and IL-2 production induced by mitogens and anti-TCR monoclonal antibodies.[587] It has been suggested that a large variety of cells can express IL-17R, including fibroblasts; epithelial; and endothelial cells.

Signal Transduction

Murine IL-17 stimulates the activity of the transcriptional factor NF-κB, which is known to regulate a number of gene products involved in cell activation and growth control, raising the possibility that some of IL-17 activities may be mediated by a common intracellular event.[65,587]

Biological Actions

Recombinant HVS13 and CTLA-8 stimulate transcriptional factor NF-κB activity and IL-6 secretion in fibroblasts and co-stimulate T-cell proliferation.[587] IL-17 and the product of its viral counterpart—ORF13—stimulate epithelial, endothelial, and fibroblastic cells to secrete cytokines such as IL-6, IL-8, and G-CSF, and PGE2. Furthermore, when cultured in the presence of IL-17, fibroblasts can sustain the proliferation of CD34 hematopoietic progenitors and their preferential maturation into neutrophils. These observations suggest that IL-17 may constitute an early initiator of the T-cell–dependent inflammatory reaction and be an element of the cytokine network that bridges the immune system to hematopoiesis. TNFα and IFNγ have been found to have additive effects on the IL-17–induced secretion of IL-6; neither IL-17 nor TNFα induces release of GM-CSF. However, the combination of IL-17 plus TNFα is effective in this event.[65,169] Knowing that IL-17 induces the production of other cytokines (IL-6, IL-8, and G-CSF) from fibroblasts, endothelial cells, and epithelial cells, the release of PGE2 enhances the expression of ICAM-1. Considering that these molecules have very different activities, a single cytokine can have a broad set of not entirely predictable effects, which may have the potential of counterbalancing each other.[66]

Interleukin-18

Interleukin-18 (IL-18) is structurally similar to IL-1 and functionally similar to IL-12. It increases the cytotoxic activity of NK cells and cytotoxic T lymphocytes and may play a role both as a neuroimmunomodulator and in the induction of mucosal immunity.[49]

Synonym

IL-18 was formerly known as IFNγ-inducing factor (ICIF).

General Characteristics

The amino acid sequence determined from the human IL-18 from normal human liver cDNA clones indicates a 193–amino acid precursor peptide with 65% homology with that of murine IL-18. The amino acid sequence of IL-18 also includes an IL-1 signature-like sequence. IL-18 possesses potent biological activities, including the induction of IFNγ production by spleen cells and the enhancement of NK-cell cytotoxicity.[544]

Other general characteristics of IL-18 include:

Molecular Weight

The molecular weight of IL-18 is though to be ~18 kDa.[112]

Cross-Reactivity

The cross-reactivity (amino acid sequence homology between human and mouse) for IL-18 is 65%.[544]

Chromosomal Location

The chromosomal location of IL-18 is unknown.

Cellular Origin

Human IL-18 is produced primarily by liver cells (Figure 22-26).[544]

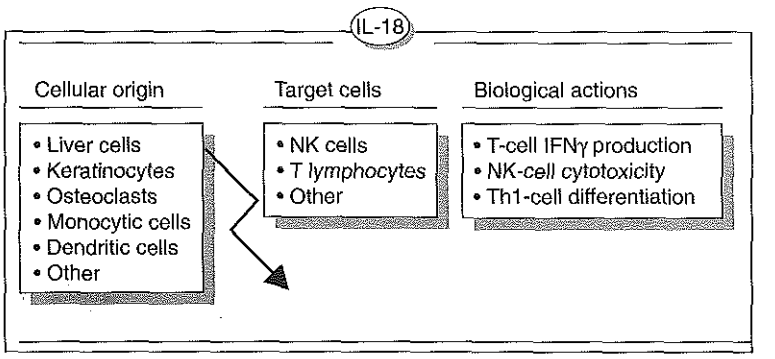

Figure 22-26 Cellular origin, principal target cells, and biological actions of IL-18.

Biological Actions

IL-18 augments NK-cell activity in cultures of human PBMCs similar to that of the structurally unrelated cytokine IL-12. In addition, it has been found to enhance the production of IFNγ and GM-CSF while decreasing the production of IL-10 by mitogen-stimulated PBMCs but had no effect on IL-4 production by concanavalin A–stimulated PBMC. IL-18 enhances T-cell proliferation apparently through an IL-2–dependent pathway. It also enhances Th1 cytokine production in vitro and exhibits synergism when combined with IL-12 in terms of enhanced IFNγ production but not IL-2 and GM-CSF production.[362,544]

IL-18 selectively enhances the FasL-mediated* cytotoxicity of cloned murine Th1 cells but not Th0 or Th2 cells. Anti-IFNγ antibody does not block the IL-18–induced cytotoxicity of Th1 cells, nor does IFNα, IFNγ, or TNFα augment the cytotoxic activity of Th1, thus indicating that this enhanced cytotoxicity of Th1 cells was mediated by IL-18. In addition, IL-12 has been found to also enhance the FasL-mediated cytotoxicity of Th1 cells, suggesting that Th1 cells possess receptors for both cytokines, although these cytokines can act via different pathways. Data indicate that IL-18 might play a potential role in immunoregulation or in inflammation by augmenting the functional activity of FasL on Th1 cells.[112]

Interferons

Interferons (IFNs) are a family of glycoproteins that exert virus-nonspecific but host-specific antiviral activity by inducing the transcription of cellular genes coding for antiviral proteins that selectively inhibit the synthesis of viral RNA and proteins. The name of IFNs derives from the common property *to interfere with the viral infection of cells.* They represent the most important element of natural immune defenses against viral infection.[152,472]

IFNs also have immunoregulatory functions (inhibition of B-cell activation and antibody production enhancement of T-cell activity, and enhancement of NK cell cytotoxic activity) and can inhibit the growth of nonviral intracellular parasites. Production of interferon can be stimulated by viral infection, especially by the presence of double-stranded RNA, by intracellular parasites (chlamydiae and rickettsiae), by protozoa *(Toxoplasma),* and by bacteria (streptococci and staphylococci) and bacterial products (endotoxins). Interferons have been divided into three distinct types (α, β, and γ) associated with specific producer cells and functions, but all animal cells are able to produce interferons, and certain producer cells (leukocytes and fibroblasts) produce more than one type (both IFNα and IFNβ).[138]

IFNα and IFNβ show little structural similarity (30% homologous at the amino acid level), but they share a common receptor, have similar functions, and both genes are located on chromosome 9. There are at least 24 structurally related subtypes of IFNα,* each encoded by a separate gene with 95% homology, and only one IFNβ gene in humans and mice (the so-called IFNβ2 is now demonstrated to be IL-6). Collectively, they are known as type I IFNs and acid-stable (pH2) IFNs. IFNγ has a different receptor and partially different functionality. It is known as type II IFN and acid-labile IFN.[1,71,436,485]

All IFNs have antiviral capacity and immunomodulatory and antiproliferative effects on both normal and tumor cells. Consequently, they have been used in the treatment of several pathologies, ranging from viral infection (e.g., common cold and viral hepatitis) and intracellular parasitosis to malignancies (e.g., leukemia, lymphoma, and melanoma). Generally, IFNs enhance the effectiveness of the cellular immune response, but their use in anticancer therapy is based on the antiproliferative effect of IFNs. This duality of increased synthesis of several proteins, such as other cytokines, MHC molecules, β2-microglobulin, carcinoembryonic antigen, enzymes, and decreased synthesis of several other proteins followed by decreased expression of the *myc* and *ras* oncogenes, is characteristic of IFNs.[485]

*Fas ligand (FasL), expressed on activated T cells, plays a central role in regulating the immune response by inducing apoptosis in activated lymphocytes through binding to its receptor, Fas.

*Some investigators now subdivide the IFNα family into the IFN I and IFN II (also known as IFNθ) groups on the basis of the number of amino acids (166 or 165 amino acids for IFNαI and 172 amino acids for IFNαII) and the respective sequences within the family.[1,71]

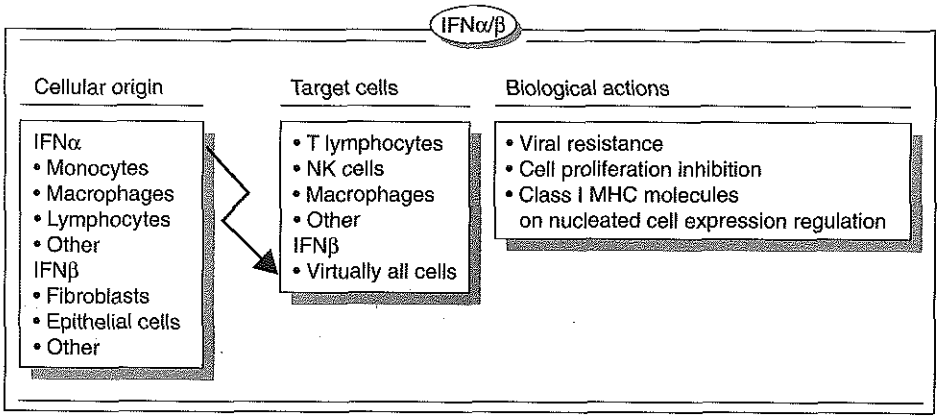

Figure 22-27 Cellular origin, principal target cells, and biological actions of IFNα and IFNβ.

IFNα and IFNβ

Interferonα (IFNα) is the major interferon produced by virus-induced leukocyte cultures; the primary producer cells are null lymphocytes, and the major activities are antiviral activity and activation of NK cells. It is used in the experimental treatment of hairy cell leukemia and other selected neoplasias.[138]

Interferonβ (IFNβ) is the major interferon produced by double-stranded RNA-induced fibroblast cultures; the primary producer cells are fibroblasts, epithelial cells, and macrophages, and the major activity is antiviral activity.[138]

Synonyms

IFNα was formerly known as acid-stable IFN, B-cell IFN, buffy coat IFN, leukocyte-derived IFN, lymphoblast IFN, Namalwa IFN, and type I IFN. IFNβ was formerly known as acid-stable IFN, fibroblast-derived IFN, IFNβ1, and type I IFN.

General Characteristics

IFNβ is glycosylated, but the majority of human IFNα type I molecules are not. The three-dimensional structure of either molecule is yet to be fully elucidated, but there may be a similarity between the two. IFNβ has five helices (three parallel to each other and two antiparallel to the other three), and the general structure is a variant of the α-helix bundle but with a new chain-folding topology common to all type I IFNs.[71,436]

Other general characteristics of IFNα and IFNβ include:

Molecular Weight. The literature values for the molecular weight of IFNα vary from 16 to 27.5 kDa. The following molecular weights have been reported: 18 kDa,[1] 20 kDa,[421] 16 kDa,[436] 19 to 26 kDa (monomer),[472] 16 to 27 kDa,[71] and 16 to 27.5 kDa.[389] The literature values for the molecular weight of IFNβ vary from 15 to 32 kDa. The following molecular weights have been reported: 20 kDa (monomer),[1,71,421,472] 27 kDa,[436] and 22 to 23 kDa.[389]

Cross-Reactivity. The cross-reactivities (amino acid sequence homology between human and mouse) of IFNs are IFNα (40%) and IFNβ (48%). IFNs are more species specific and preferential in their biological activities than most other cytokines.

Chromosomal Location. The chromosomal locations of α and β IFN and their receptors are 9p22 (IFNα), 9p22 (IFNβ), and 21q22.1 (IFNαBR, shared with IFNβ).

Cellular Origin. IFNα is produced by monocytes, macrophages, lymphocytes, and cellular lines such as Namalwa and KG1 (Figure 22-27). IFNβ is produced by fibroblasts and epithelial cells. However, many other cells can also produce these cytokines, including hematopoietic cells for IFNα.[71,152,341,436]

Monocytes differentiate into macrophages during cell culture and lose their ability to produce IFNα when challenged with HIV-1. However, these cells remain capable of producing IFNα in response to other stimuli, suggesting that as monocytes differentiate into macrophages, they selectively lose their ability to produce IFNα through the double-stranded RNA (dsRNA)–independent mechanism.[173]

Control of Synthesis and Release

Viral infection is the most potent signal that elicits type I IFN production. Both IFNα and IFNβ are also secreted during immune responses to antigens (antigen-activated T cells stimulate mononuclear phagocytes to synthesize type I IFNs).[1] IFNα production is increased if the cellular source is previously exposed to either IFNα or IFNβ. IFNβ synthesis is enhanced by bacterial endotoxins, TNFα, and IL-1.[472] Data suggest that there are dsRNA-dependent and dsRNA-independent mechanisms for the induction of IFNα production.[173] Glucocorticoids regulate IFNα production (inhibition) but fail to elicit this activity from acquired immunodeficiency syndrome (AIDS)–glucocorticoid resistant monocytes.[393]

IFNα and IFNβ Receptors

The receptors for IFNα and IFNβ are shared and consist of a single-chain polypeptide (CD118) that is homologous to the type II IFN. Two types of receptors have been cloned.

The first specifically binds IFNαB (IFNα8, a variety of IFNα) and is known as the IFNαB receptor. The second binds both IFNα and IFNβ and is called the IFNα/β receptor. The IFNαβR is a member of the class II cytokine receptor family, which also includes the IFNγR, IL-10R, and tissue factor. The IFNα/βR is also a class II cytokine receptor and contains at least two components that interact with type I IFNs. It is not known if these two receptors are expressed independently on the cell surface or are associated with each other in an IFN receptor complex. The receptors are present on most types of cells. A soluble form of the IFNα/βR has been identified in human serum and urine.[1,71,152,335]

Signal Transduction

Receptor signaling results in phosphorylation and activation of PTK, TYK2, and JAK1 but not KAK2. Although IFNα activates STAT1α and STAT5, STAT1α is predominantly activated. Differential phosphorylation and consequent differential activation of both separate and overlapping STAT proteins by IL-2, IL-12, and IFNα may provide a molecular basis for the similarities and differences in the actions of these cytokines on NK cells. IFNα has also been shown to activate PLC-A2 releasing arachidonic acid and DAG. The IFNα/βR is physically associated with JAK1.[71,591]

Biological Actions

Antiviral action was the first biological property of IFNα and IFNβ to be described. However, type I IFNs also (1) inhibit cell proliferation; (2) induce MHC class I expression on cell surfaces (representing cellular targeting for the immune system); (3) increase the cytolytic activity of NK cells, macrophages, and Tc lymphocytes; and (4) improve ADCC.[1,71,472,485] This results in the enhancement of particular host-nonspecific responses against intracellular pathogens, tumor cells, and graft cells. Inhibition of viral replication is based on the induced synthesis of a number of enzymes that interfere with replication of viral RNA or DNA. This antiviral action is primarily paracrine (a virally infected cell secretes type I IFNs [typically IFNβ] to protect neighboring cells not yet infected, thus limiting the area of infection and the extent of cellular damage). IFNβ is a physiological inhibitor of normal cell growth, and IFNα is an antiproliferative molecule for certain tumors as will be discussed later. Inhibition of cell growth and proliferation may result from the induction of the same enzymes that inhibit viral replication and possibly other ones that prevent synthesis of essential amino acids. Inhibition may also result from the inhibitory effect in the production of hematopoietic growth factors that originate in the bone marrow microenvironment.[8] MHC class I expression is increased by type I IFNs in parallel to a profound inhibition of class II expression. This MHC modulation boosts the effector phase of CD8 T cells (Tc response), preventing the activation of class II–restricted CD4 T cells.[1,472] Several activities are probably involved in the antiinflammatory effects mediated by IFNβ, including complex immunoregulatory effects on endothelial cells with differential modulatory effects on various cell surface markers.[363] The effects of IFNβ on T-cell functions in vitro are centered on the inhibition of T-cell proliferation and T-cell–dependent Ig secretion in a dose-dependent manner. IFNβ does not inhibit up regulation of CD40L on activated T cells but blocks induction of CD25 on stimulated T and B lymphocytes. Secretion of IFNγ, TNFα, and IL-13 is inhibited by the addition of IFNβ, whereas IL-4 secretion is unaffected. IFNβ also enhances secretion of IL-2 and of IL-10.[345] Moreover, the influence of IFNα on CD4 T cells is very important through cytokine synthesis and Th1/Th2 polarization. IFNα also markedly inhibits IL-5 production and stimulates production of IL-10 in activated CD4 T cells. This effect might enhance the negative-feedback mechanism ascribed to IL-10, which limits inflammatory reactions and contributes to CD4 polarization.[8,379,462] Most T cells derived in the presence of IFNα produce IFNγ but no or only limited amounts of IL-4 and IL-5 (Th1 or Th0 cells). IFNα also shifts the TCR Vβ repertoire of specific T-cell lines.[410] However, neither IFNγ nor IFNα alone can induce Th1 polarization.[571] IFNα also induces a variety of central actions (e.g., fever, anorexia, slow wave sleep, and depression). The cellular mechanism by which this cytokine affects neuronal activity appears to be the suppression of the N-methyl-D-aspartate (NMDA) responses through its action on opioid receptors and the production of free radicals, such as hydroxyl radicals and NO, caused by the neuron-glial cell interactions.[261] Systemic administration of human IFNα stimulates the pituitary-adrenal axis in humans, but the exact mechanism still remains to be established. However, circulating IL-6 increases, resulting in activation of the pituitary-adrenal axis.[479]

Clinical Relevance

IFNα is an antiviral cytokine detected in plasma of HIV-infected patients during acute viremia and during late-stage disease.[173] It is known to inhibit expression of GM-CSF in adherent cells of human long-term bone marrow cultures stimulated with IL-1, TNFα, or endotoxin. These results indicate a regulatory role for IFNα in the bone marrow microenvironment possibly involved in the myelosuppressive effect of IFNα therapy on viral infections.[194] Both hyperthyroidism and hypothyroidism have been reported during prolonged recombinant human IFNα therapy. These changes in thyroid hormone metabolism are possibly mediated in part by IL-6.[98] Undetectable IFNα serum levels in a patient with atopic dermatitis with normal IL-4 and increased IFNγ suggest the role of IFNα in the pathogenesis of atopic dermatitis.[134]

Therapeutic Applications

Type I IFNs have clinical application in the treatment of viral infections, especially infections characterized by a tendency toward a chronic state (such as hepatitis B and C). Also, IFNs have potential as adjuvants in the treatment of HIV infection. Their antitumor effects are significant (especially

IFNα) in leukemia, lymphoma, multiple myeloma, melanoma, renal cell carcinoma, and Kaposi's sarcoma. Side effects include flulike syndrome, fever, myalgias, rashes, thrombocytopenia, and neutropenia.[472,485]

Some therapeutic results have been encouraging: Treatment with IFNα of a posttransplant lymphoproliferative disorder led to dramatic clinical, radiographic, and histological improvement probably directly related to the inhibition of Th2 CD4 lymphocytes.[160] IFNα modulates the development of allergen-specific T cells in vitro, which suggests that it may represent a useful tool for novel immunotherapeutic approaches in allergic disorders.[410] Also a growing body of evidence indicates that IFNα has a major place in the long-term treatment of idiopathic hypereosinophilic syndrome, especially in cases resistant to conventional treatment.[340] Results from clinical trials have indicated that recombinant IFNβ is a promising drug for the treatment of multiple sclerosis, although this treatment decreases TNFα and increases IL-6, which could potentially counteract its beneficial immunomodulatory effects[63,435]; it has been suggested that IFNβ gene transfection by the use of liposome coupled with a monoclonal Ab might become a useful technique for gene therapy of malignant glioma.[557] However, a phase II trial of IL-2 and IFNα in the treatment of metastatic colorectal carcinoma has shown that the toxicity and short duration of response without survival benefit do not support the routine use of this therapeutic modality for this type of tumor.[82]

IFNγ

Interferonγ (IFNγ) is the major interferon produced by immunologically stimulated (by mitogens or antigens) lymphocyte cultures; the primary producer cells are T lymphocytes, and the major activity is immunoregulation. IFNγ has been implicated in aberrant expression of class II histocompatibility antigens by tissue cells (such as thyroid cells) that do not normally express them, leading to autoimmune disease.[138]

Synonyms

IFNγ was formerly known as immune IFN, macrophage activating factor, T-cell IFN, and type II IFN.

General Characteristics

IFNγ is a homodimer (native IFNγ is a monomeric glycoprotein, but the active moiety is a dimer, which interacts with α- and β-receptors causing their aggregation and subsequent activation) formed by antiparallel association of two subunits. Each subunit has six α-helices held together by short nonhelical sequences. There are no β-sheets. The subunits have a flattened elliptical shape, whereas the overall structure of the dimer is globular.[71]

IFNγ was originally described as an antiviral molecule but is a pleiotropic cytokine influencing the growth, differentiation, and function of T cells, B cells, NK cells, macrophages, and other types of cells, such as endothelial cells and fibroblasts. It is involved in the regulation of almost all phases of the immunoinflammatory responses. Because IFNγRs are expressed on almost all types of cells, this cytokine directly mediates a vast biological spectrum.[472] However, it has low antiviral and antiproliferative activity but potentiates the antiviral and antitumor effects of IFNα and IFNβ.[71,341]

IFNγ binds with high affinity to heparin sulfate and heparin molecules through its carboxyl-terminal domain. In vivo, IFNγ is eliminated from the blood stream with a half-life of 1.1 minutes, caused by binding to heparin sulfate. Unbound IFNγ is cleaved rapidly at the carboxyl-terminal side, a process that inactivates the cytokine. When bound to heparin, the plasma clearance of IFNγ is greatly decreased (half-life ≅99 minutes), and the cytokine activity is increased by as much as 600%. These data demonstrate that the blood clearance of IFNγ is a nonreceptor-mediated process and that in vivo the local concentration of heparin sulfate and/or heparin-like molecules regulates the activity of this cytokine.[330]

Other general characteristics of IFNγ include:

Molecular Weight. Depending on its molecular form and extent of glycosylation, the literature values for the molecular weight of IFNγ vary from 20 to 70 kDa. The following molecular weights have been reported: 20 to 25 kDa (dimer),[341,389,472] 21 to 24 kDa subunits (the size variation is due to variable degrees of glycosylation, but each subunit contains an identical 18 kDa polypeptide),[1] 45 kDa (normally dimerized),[421] 40 to 70 kDa,[436] 20 and 25 kDa forms (these two glycosylated forms are caused by the post-translational modification of a 17 kDa polypeptide, but the extent of glycosylation is variable and not necessary to the biological activity),[152] 20 or 25 kDa (corresponding to different species of monomeric human IFNγ, which differ only in the degree and sites of glycosylation), and 40 to 70 kDa (caused by dimerization and some multimerization).[71]

Cross-Reactivity. The cross-reactivity (amino acid sequence homology between human and mouse) of IFNγ is 40%.[71] It has no significant cross-species activity.

Chromosomal Location. The chromosomal location of IFNγ and its receptor are 12q24.1, 6q12-q22, and 21q22 (AF-1).

Cellular Origin. IFNγ is synthesized by activated T cells (CD4 Th0, CD4 Th1, and CD8) and NK cells (Figure 22-28).*

Control of Synthesis and Release

IFNγ is produced by CD4 Th1 cells following antigen activation.[380] Transcription is directly initiated after antigen activation and is enhanced by IL-2, IL-12, and IL-15. Depending on the type of antigenic stimulus, Th1 CD4 T cells and CD8 T cells are the main producers of IFNγ. CD40/CD40L interaction synergizes with IL-12 in selectively enhancing IFNγ production through purified anti-CD3-stimulated T cells. Both CD4 and CD8 T cells are able to produce IFNγ in the

*References 1, 19, 71, 152, 341, 472.

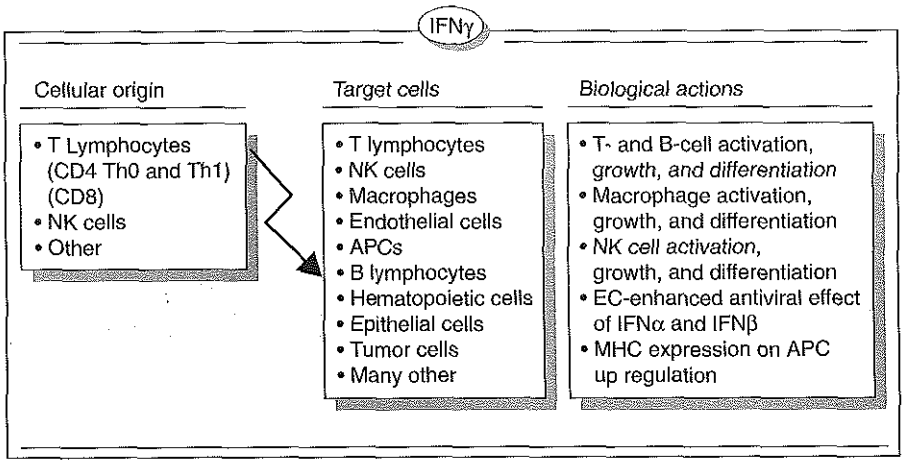

Figure 22-28 Cellular origin, principal target cells, and biological actions of IFNγ.

presence of helper signals from IL-12 and CD40, although CD8 T cells are less active.[416] Th1 cells can be the primary producers of IFNγ when exposed to antigens, but on appropriate stimulation, NK cells are potent producers; when exposed to IL-1, IL-2, and IL-12, they become the primary source of IFNγ.[1,152,185,341,469] IL-12 is a very critical factor for skewing the immune response toward a Th1 of cytokine profile (high IFNγ and low IL-4) and is thought to be a key factor for the induction of IFNγ synthesis.[216,242] IL-18 has been found to enhance the production of IFNγ. When T cells were exposed to a combination of IL-18 and IL-12, a synergistic effect was observed in the production of IFNγ.[362,544] The bacillus Calmette-Guerin may exert part of its antitumor action on melanoma through the induction of IFNγ, which can be greatly enhanced through the concomitant addition of IL-2 or GM-CSF.[178] Bacterial DNA induces NK cells to produce IFNγ in vivo and is associated with an increase in LPS-induced TNFα and IL-6 release.[101]

PGE2 inhibits the secretion of IFNγ, and the net IFNγ production of CD4 T cells is largely determined by the ratio of IL-12 and PGE2 at the point of T-cell activation.[217] Retinoic acid inhibits IFNγ synthesis when the CD28 costimulatory pathway is activated in addition to the TCR/CD3 pathway, suggesting that it blocks some step in the CD28 pathway.[73] Cyclosporin A inhibits IFNγ production by preventing the activation of key promoter sites, in particular, the binding of NFAT.[72]

Receptor (IFNγR)

All human cells are thought to have the IFNγ receptor; it is a complex of a high-affinity IFNγ binding chain (CD119) and a second accessory protein required for signal transduction. This specific receptor is different from, but structurally related to, the receptor used by IFNγ and IFNβ. The IFNγ binding subunit is a single-chain transmembrane glycoprotein. Although the receptor binds IFNγ with high affinity, signal transduction requires a species-specific accessory protein, which associates with the extracellular domain of the receptor. The accessory subunit has been called accessory factor 1 (AF-1) and the IFNγ receptor β-chain (being CD119 the α-chain). It is a type I membrane-spanning glycoprotein and a member of the class II cytokine receptor family. The IFNγR is also a member of the class II cytokine receptor family, characterized by an extracellular region of about 200 amino acids but no WSXWS motif characteristic of class I cytokine receptors.

The IFNγR is expressed on a wide variety of hematopoietic cells, including T cells, B cells, macrophages, PMNs, and platelets. It is not expressed by erythrocytes. The receptor is also on many somatic cells, such as epithelial and endothelial cells, and on many tumor cells. The receptor density ranges from 200 to 10,000 per cell. Membrane-bound IFNγ is rapidly internalized and degraded at 37 °C.[1,71,152]

Signal Transduction

IFNγ induces receptor dimerization and internalization, but its receptor-mediated ligand internalization is not sufficient to induce a biological response.[39] Signal transduction is mediated by phosphorylation and activation of JAK1 and JAK2 PTKs and involves phosphorylation of the receptor. The IFNγ and IFNα/β receptors share common signal transduction components, including p91, which binds directly to the GAS response element after translocation to the nucleus.[71] With the use of chimeric receptors involving the IFNγR complex as a model system, it has been demonstrated that JAK2 activation is not an absolute requirement for IFNγ signaling because other members of the JAK family can functionally substitute for JAK2.[285] STAT1 transcription factor is activated by IFNγ, synthesized, and released on stimulation of T-lymphocyte populations. There is evidence that Th1 cells lack the IFNγR chain necessary for activation of STAT1.[190]

Biological Actions

IFNγ shares many biological actions with type I IFN (it has antiviral activity and antiproliferative effect). As IFNγ enhances the antiviral activity of IFNα and IFNβ in a synergistic fashion, production of IFNγ by specific T cells is an

important pathway by which the immune system is able to enhance the nonspecific protection against intracellular infection.[472] However, IFNγ has several properties that are especially attributed to this cytokine.*

Macrophage and Lymphocyte Functionality. IFNγ is a powerful activator of macrophage functionality (NO, superoxide, TNFα, IL-1 production, and Fc receptors increase) and has a very important role in cellular cytotoxicity, providing the means by which T lymphocytes activate macrophages. The diverse effects of IFNγ converge to promote Th1 polarization and macrophage inflammatory reactions, while suppressing Th2 and eosinophil-dependent responses; it thus has an essential role in the destruction of intracellular pathogens. However, in the differentiation of CD4 cells to a Th1 phenotype, the role for IFNγ is controversial. With optimal TCR stimulation and co-stimulation, endogenous IFNγ, without IL-12, is sufficient to elicit Th1 cells via an autocrine mechanism. With suboptimal stimulation, exogenous rIFNγ or rIL-12 is required for Th1 development, and optimal development of the Th1 phenotype is mediated by the synergistic actions of both cytokines. Human peripheral blood T cells that are stimulated through the TCR and expanded with IL-2 are unresponsive to IFNγ. This nonresponsiveness occurs because of a lack of expression of the AF-1 of the IFNγR, while at the same time maintaining IFNγR CD119 expression. Expression of the AF-1 can be restored by secondary TCR ligation or phorbol myristate acetate (PMA) treatment. Therefore as T cells progress from primary TCR activation through IL-2–dependent proliferation, followed by secondary TCR stimulation, their responsiveness to IFNγ varies, and this may affect their ability to participate in an ongoing immune response.

Major Histocompatibility Complex Class I and II Expression. INFγ is the principal enhancer of MHC class I expression on many different types of cells. In contrast to type I IFN, it is also an inducer of MHC class II expression in APCs (mast cells included) and lymphocytes, promoting the activation of class II–restricted CD4 T cells. These cells are an important target for IFNγ, leading to the differentiation of the Th1 subset and inhibiting the proliferation of Th2 cells.

Antigen Presentation. Both IFNγ and IL-10 are thought to suppress antigen presentation by Langerhans' cells for Th1 cells by suppressing their CD80 (B7-1) expression. The inhibitory effect of IFNγ on CD80 expression on Langerhans' cells appears to be partially mediated through the suppression of GM-CSF production by keratinocytes.

Cellular Adhesion. The previously discussed effects of IFNγ on CD4 cells are complemented by its enhancement of adhesion and morphological alterations on cells that facilitate lymphocyte extravasation to tissue and the expression of CD54 adhesion molecules (ICAM-1) fundamental in binding effector lymphocytes to target cells. Treatment with TNFα plus IFNγ causes PECAM-1 to decrease or disappear from endothelial cells' intercellular contacts. This phenomenon is accompanied by a reduction of leukocyte migration through endothelial cell monolayers. On the basis of several observations, it has been suggested that a primary role for IFNγ is to promote intercellular adhesion between the leukocytes in an effector focus, promoting its ability to block pathogen migration. Monocytes stimulated with exogenous IFNγ lose their capacity to bind to fibronectin, which coincides with the down regulation of surface α5 integrin expression. Although IFNγ-treated monocytes also show a decreased ability to adhere to laminin, no alteration of β2 integrin expression is detectable, thus suggesting a modification of the functional state of surface β2 integrins. Furthermore, when stimulated with TGF1, IFNγ-pretreated monocytes reacquire the ability to bind to fibronectin and laminin. Conversely, IFNγ reduces adhesiveness to fibronectin and laminin of monocytes initially stimulated with TGFβ1. These in vitro adhesive-deadhesive responses of monocytes to TGFβ1 and IFNγ modulation may reflect mononuclear phagocyte motility within sites of inflammation.

T-Cell Cytotoxicity and Acute Phase Response. The maturation of CD8 Tc lymphocytes is dependent on IFNγ, which acts synergistically with other cytokines (e.g., with TNFα).[84] As an inducer of cellular cytotoxicity, IFNγ is a less potent activator than TNF, up regulating the respiratory burst of neutrophils, but much more potent than type I IFNs, stimulating the activity of NK cells. IFNγ also augments the APR, increasing the production of IL-1 and TNF. IFNγ can be an important regulatory cytokine in chronic inflammatory sites, and its purported antiinflammatory effects may be explained by significant suppression on the induction of IL-1β gene expression in macrophages.

Immunoglobulin Production. IFNγ produced by T and NK cells after CpG DNA stimulation contributes to the B-cell secretion of IL-6 and the subsequent Ig production.* However, IFNγ inhibits IgM secretion, which is triggered by a different bacterial product, LPS. Thus in contrast to its antagonistic interaction with LPS, IFNγ causes a dose-dependent increase in the level of IgM secretion induced by CpG DNA. Like IgM secretion, B-cell secretion of IL-6 more than doubles after the addition of exogenous IFNγ.[589]

Other Activities. IFNγ causes a concentration-dependent decrease in steady-state lipoprotein receptor-related protein (LRP) mRNA expression and gene transcription rate. When TGFβ1 is added 24 hours before IFNγ, the extent of LRP down regulation is reduced. This suggests

*References 1, 16, 32, 35, 61, 89, 149, 154, 232, 241, 332, 341, 404, 440, 454, 471, 472, 485, 497, 549, 578.

*The dinucleotide CpG is significantly under-represented in vertebrate DNA and is usually methylated. In contrast, CpG dinucleotides are generally present at the expected frequency in bacterial DNA and are unmethylated. These unmethylated CpG motifs induce B cells to secrete IL-6 and IgM and can induce NK and CD4 T cells to produce the immunoregulatory IFNγ.

TABLE 22-6 Principal Cellular Actions of IFNγ[1,341,436,472,485]

Cell Type	Biological Effects
Many cells*	Enhanced MHC class I expression (antigen recognition by CD8 Tc cells)
APCs	Enhanced MHC class II expression (antigen recognition by CD4 cells)
Stem cells	Inhibition of hematopoiesis
B cells	Growth and differentiation (late-acting agent);† inhibition of proliferation‡
T cells	Differentiation and activation (synergizes with IL-2); inhibition of proliferation†
Monocytes	Differentiation into macrophages
Møs	Effector activation (together with TNFα)
Neutrophils	Activation, adhesion to endothelium
NK cells	Activation (synergizes with IL-2)
Endothelial cells	Activation, enhanced MHC expression
Tumor cells	Enhanced susceptibility to Tc and NK cells (synergizes with TNFα)

*Do not normally express IFNγ.
†Synergistically with other B-cell stimulating factors.
‡Dependent on its capacity to inhibit protein synthesis.

that the balance between IFNγ and TGFβ1 may be critical in determining LRP expression at sites of infection and inflammation. The results from LRP being a major receptor for multiple ligands, including chylomicrons and very low-density lipoprotein remnants, bacterial toxins, viruses, proteinases, lipoprotein lipase, and activated α_2-macroglobulin. In contrast to Th2 cell–associated cytokines, IFNγ does not affect PGE2 production and cyclooxygenase activity.

Experimental data support the hypothesis that IFNγ is antifibrogenic; this may be a consequence of cytokine therapy. Some of the most important classical cellular actions of IFNγ are summarized in Table 22-6.

Clinical Relevance

Humans with deficient IFNγ response show several immunological defects, such as increased susceptibility to infections with intracellular pathogens. Impaired IFNγ production has been demonstrated in human pathological conditions, namely chronic mucocutaneous candidiasis[320] and systemic lupus erythematosus.[206]

Increased IFNγ production is associated with food-sensitive atopic dermatitis,[482] Crohn's disease (local mucosal synthesis),[180] RA synovial tissue (suggesting a role for this cytokine in the ongoing immunological reaction of the inflamed joint),[136] and poor antibody-mediated immunity in hypovitaminosis A. IFNγ in relatively small amounts can limit Th2 cell growth and interfere with the B-cell stimulatory functions of Th2 cell cytokines.[73]

IFNγ has also been found to be associated with immunodeficiency after allogeneic bone marrow transplantation,[287] the pathophysiology of aplastic anemia,[470] and atherogenesis.[481]

Detection in carcinoma tissue of IFNγ mRNA that leads to the induction of the HLA-DR antigen on adjacent normal cells may be an indicator of a host's immune response to carcinoma. This in vivo observation might be clinically applicable to the prediction of patients' immune responsiveness to carcinomas.[350]

Therapeutic Applications

Based on a broad spectrum of activity, IFNγ is of great pharmaceutical interest with a wide variety of clinical expectancy, including antiviral, antiproliferative, and immunomodulatory effects.[279] However, the thermodynamic stability of recombinant IFNγ is low, limiting its clinical application. New research has indicated that the insertion of additional new disulfide bonds will enhance the thermodynamic stability and protect the protein against proteolytic degradation, resulting in better pharmaceutical characteristics.[203]

As a macrophage activator, IFNγ is responsible in part for the increased ability of this cell to kill intracellular pathogens and tumor cells. However, IFNγ only partly activates mononuclear phagocytes to kill tumor cells, a function that probably requires the action of second signals, such as TNF.[1] To be an important stimulus for the TNF, IL-1, and IL-6 cytokine cascade, it antagonizes the bone-resorbing effects of these cytokines, which may be important for the treatment of RA.[472] As an inhibitor of cell growth and proliferation, IFNγ has been used to treat malignancies; however, its immunotherapeutic effect gives mixed results.[152]

Some investigators believe that the most important therapeutic application of IFNγ will be to revert or maintain a Th1 preferential response basically necessary for diverse successful defense reactions (e.g., against intracellular pathogens—namely parasites and virus—and tumor cells). IFNγ has also been shown to be a suppressor of β-amyloid precursor protein promoter activity and is the first cytokine reported to possess such down regulating effects. Attenuating β-amyloid precursor protein gene expression may have relevance in diseases such as Alzheimer's disease, in which this protein has been implicated in neuropathological processes.[439]

Using retrovirus-mediated somatic gene transfer techniques to produce IFNγ from human peripheral blood CD34 hematopoietic progenitor cells, IFNγ was found to activate monocytes that may be specifically suited to cellular therapy requiring homing to sites of inflammation where their antimicrobicidal, cytotoxic, and APC functions play an important role in host defense against foreign pathogens.[4]

At least theoretically, IFNγ and also IL-12 and IL-18, either alone or in combination, have therapeutic potential for inhibiting the synthesis of IgE.[264]

Tumor Necrosis Factors

Tumor necrosis factors (TNF) are lymphokines that exist in either an α or β form; they are capable of causing in vivo hemorrhagic necrosis of certain tumor cells, but not affecting normal cells. They also have been used as experimental anticancer agents but can also induce shock when bacterial endotoxins cause their release. TNFα contains 157 amino acids and is produced by macrophages, eosinophils, and NK cells. TNFβ is a lymphotoxin and contains 171 amino acids.[138]

Synonyms

TNFα was formerly known as cachectin, cytotoxin, cytotoxic factor, differentiation-inducing factor, hemorrhagic factor, macrophage cytotoxic factor, macrophage cytotoxin, and necrosin. TNFβ was formerly known as cytotoxin, differentiation-inducing factor, and lymphotoxin (LT). Although TNFβ and LT are considered synonyms, some authors prefer the restricted equivalence of TNF to TNFα, and consider LT to be a different related cytokine.[1,71]

LTα and TNFβ have been found to be structurally similar and biologically indistinguishable. LTβ is a type II integral membrane-bound protein of 33 kDa that forms a heteromeric complex with LT on the cell surface without a known function.[71]

General Characteristics

TNFα and TNFβ are closely related proteins and may have arisen by ancestral duplication of a common gene.[472]

TNFα is expressed as a type II membrane protein attached by a signal anchor transmembrane domain and is processed intracellularly by an enzyme called ADAM-17 (a disintegrin and metalloprotease domain17; also referred to as TACE [TNF-alpha converting enzyme] and TACA [TNF-alpha converting activity]). It is synthesized as a nonglycosylated protein of approximately 25 kDa whose orientation is reversed (its amino terminus is intracellular, and its carboxy terminus is extracellular). After its synthesis, latent pro-TNFα (a 26 kDa protein) is deposited on the cell surface of monocytes and other cells. ADAM-17 cleaves pro-TNFa, releasing an active, soluble 17 kDa form. Other proteolytic functions of ADAMs include shedding of members of the family of TNF receptors and other cell-surface cytokines, adhesion molecules, and growth factors and receptors that are involved in inflammation, cell proliferation, and cell death.[474] The 17 kDa membrane fragment, including the carboxy terminus, is proteolytically cleaved by a matrix metalloproteinase from the plasma membrane of the mononuclear phagocytes and assembled into a stable 51 kDa to 52 kDa biologically active homotrimer (secreted form).[1,71,152]

Secreted TNF assumes a triangular pyramidal shape with each side of the pyramid being formed by a different monomeric subunit. This pyramidal shape is characterized by an edge-to-face association of the antiparallel sandwich structure of the wedge-shaped monomers. The receptor binding sites are at the base of the pyramid, allowing simultaneous binding to more than one receptor. The tertiary structure is very similar to the so-called "jelly roll" motif of some plant and animal virus capsids.[1,71]

TNFβ is also a homotrimer cytokine and shares approximately 30% to 35% sequence homology with TNFα. It binds to the same receptors, contains one or two N-linked oligosaccharides (accounting for the variability in molecular weights), and is a truly secretory protein with a normal signal peptide and without a membrane-spanning region.[1,71,152]

TNFβ also exists in membrane form when bound by a transmembrane protein (LTβ), resulting in a cell-surface complex that mediates the effects of TNFβ on other cells. Both proteins belong to a general family that includes CD40L, CD30L, and CD29L.[1,341]

In general, the quantities of TNFβ synthesized are much less than those of TNFα. Consequently, TNFβ is not easily detected in the circulation and is usually considered a locally acting paracrine factor and not a mediator of systemic injury. Like TNFα, it has many biological functions, from stimulation of fibroblasts and killing of tumor cells to modulation of immunoinflammatory responses. However, TNFα is a potent paracrine and endocrine mediator of immunoinflammatory reactions. It is also known to regulate growth and differentiation of a wide variety of types of cells and to be cytotoxic (especially in combination with IFNγ) for many transformed cells. In vivo it promotes necrosis of murine sarcomas.[1,71]

TNFα and TNFβ also are thought to have unique and critical roles both in the development of the immune system and in immune responses to specific pathogens.[71,472]

Other general characteristics of TNFs include:

Molecular Weight

Depending on their molecular form, the molecular weights of TNFs vary from 17 to 70 kDa. The following molecular weights have been reported for TNFα: 17 kDa,[152,341,389,421,472] 35 kDa (trimer),[436] and 52 kDa (trimer).[71] The following have been reported for TNFβ: 25 kDa,[71,341] 21 to 24 kDa (lymphotoxin),[1] 17 kDa,[421] 60 to 70 kDa (trimer),[436] 20 kDa,[472] and 24 kDa.[152]

Cross-Reactivity

The cross-reactivities (amino acid sequence homology between human and mouse) for different TNFs are TNFα (79%) and TNFβ (74%).[71] There is a significant cross-species reactivity. However, human TNF binds to the mouse p55 receptor but not to the mouse p75 receptor. Mouse TNF binds to both human receptors.

Chromosomal Location

The chromosomal location of both TNFα and TNFβ is 6p21.3. Genes lie within the class III region of the MHC. The location of TNFα, TNFβ, and LTβ within the MHC region gives the possibility that these proteins may be implicated in

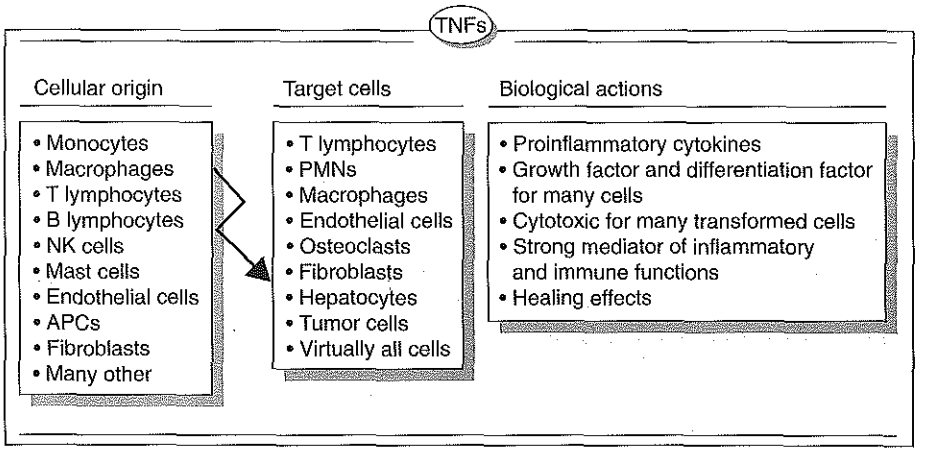

Figure 22-29 *Cellular origin, principal target cells, and biological actions of TNFs.*

some MHC-linked genetic effects.[341] The chromosomal locations of their receptors are 12p13 (type I receptor) and 1p36-p32 (type II receptor).

Cellular Origin

TNFα is produced primarily by activated monocytes and/or macrophages and, to a lesser extent, by many other types of cells, such as activated T cells (Th1 cells), B cells, NK cells, mast cells, endothelial cells, fibroblasts, keratinocytes, *microglia, astrocytes, Kupffer's cells, smooth muscle cells,* synovial lining cells, and basophils (Figure 22-29).*

Unlike TNFα, cellular sources of TNFβ are few, mostly activated T and B cells, NK cells, and astrocytes.† TNFα is produced by 0.7% to 20% of PBMCs. The primary sources of this cytokine are CD14 monocytes and/or macrophages. A significant positive correlation is found in the frequency of cells secreting IL-6, IL-10, and TNFα ex vivo, suggesting that the release of such cytokines is coordinately regulated.[205]

Control of Synthesis and Release

TNFα is released in response to bacteria (endotoxins and LPS), viruses, protozoa, cytokines (GM-CSF, IL-1, IL-2, IFNγ, *and TNFα itself*), *immune complexes,* complement component C5a, neuropeptide substance P, and reactive oxygen intermediates. Unlike TNFα, sources of preformed TNFβ have not been identified.[341,472]

Production of TNFα is inhibited by IL-10, TGFβ, cyclosporin A, PGE2, dexamethasone, ibuprofen, methylprednisolone, and pentoxifylline. Adenosine agonists inhibit TNFα production in macrophages and monocytes, but the mechanism for doing this is unknown. Nitrite exposure of LPS-stimulated alveolar macrophages resulted in a functional impairment of TNFα production. Endurance also down regulates ex vivo TNFα production.‡ An additional biological role for C3a and C3a desArg is its regulation of TNFα and IL-1β synthesis. C3a desArg may enhance cytokine synthesis by adherent monocytes at local inflammatory sites, while inhibiting the systemic synthesis of proinflammatory cytokines by circulating cells.[511]

Up regulation of TNFα production is activated by NO, *reactive oxygen intermediates, nonsteroidal antiinflammatory drugs,* and hypoxia.[122,196,211,537] The increased cytokine production during hypoxia may be due to decreased PGE2 synthesis. PGE1 suppresses T-cell adhesion to endothelial cells by selectively inhibiting TNFα-induced up regulation of ICAM-1 on these cells.[211,569]

The α-subunit of the heterotrimeric G protein, Gz, can regulate production of TNFα, modulating the stimulatory pathways for induction of this cytokine synthesis in mast cells.[34]

A20 (a zinc finger protein—a product of a cytokine-induced primary response gene) has been found to specifically inhibit signal transduction pathways induced by TNF and IL-1, *suggesting that it functions as a negative regulator* of the cytokine response.[238]

Postranscriptional regulation may be accomplished by controlling the rate of precursor mRNA splicing of TNFβ and message stability of both TNFα and TNFβ.[341]

Receptor (TNFsR)

Two different TNF receptors of 55 and 75 kDa, each encoded by a separate gene, bind both TNFα and TNFβ. Although all types of cells, including both TNF-sensitive and TNF-resistant cells, express *TNFsRs (with few exceptions, such as* erythrocytes and resting T cells), the type I (TNFR-1, type B, p55, CD120a) receptor is expressed on many different types of cells, and the type II (TNFR-2, type A, p75, CD120b) receptor is expressed predominantly on hematopoietic cells.[1,71,341,472] Both receptors contain four cys-rich repeats in the extracellular domain. The two receptors are members of the nerve growth factor receptor (NGFR)/TNFsR superfamily and are less than 25% identical. (They have similar homology to each other and to other members of the

*References 1, 11, 71, 152, 341, 420, 432, 472, 485.
†References 1, 152, 299, 341, 421, 432, 436, 472.
‡References 1, 3, 34, 48, 273, 427, 453, 472, 540.

superfamily.) There is also no significant homology between the intracellular domains of the two TNFαs receptors, indicating different signaling mechanisms. Receptor density ranges from 2000 to 3000 binding sites per cell, and the amount of cell lysis is proportional to the number of TNF molecules bound to susceptible cells. The affinity of TNFs for these receptors is unusually low for a cytokine (k_d of 5×10^{-10} mol for type II receptor and 1×10^{-9} mol for type I); however, TNF is synthesized in very large quantities and can easily saturate its receptors.[1,71,152] Each of these receptors has a large cytoplasmic domain and can transmit signals through the NF-κB pathway that give rise to most of the immunological effects of TNFα.

The role of TNFR-1 and TNFR-2 in mediating the capacity of TNFs to stimulate NGF production in fibroblasts has been investigated, indicating that TNFR-1 alone mediates the TNF's activity to stimulate NGF production in fibroblasts.[210] The role of the two TNFRs in discriminating TNFα and LTα (TNFβ) effects has been studied. Data suggest that LTα is less potent than TNF because of its lower ability to properly trigger the p55 TNFR and because of its lack of signaling through the p75 TNFR.[357] In addition, whereas the p75 TNFR can both directly propagate TNF signals and "pass" TNF to the p55 TNFR, it attenuates LTα and may serve as a decoy receptor for this cytokine.[356]

In general, TNFR-1 is the principal mediator of TNFα activity, with TNFR-2 serving an auxiliary role. Moreover, unlike TNFR-2, the cytoplasmic portion of TNFR-1 includes an 80–amino acid sequence known as the death domain, which is also found in the Fas protein. Receptor expression is modulated by vitamin D3, IL-1, IL-2, GM-CSF, and TNF itself.[341]

Activated cells shed their TNF receptors and soluble forms of both the human p55 and p75 receptors; they have been found in serum of cancer patients and in urine. They may act as competitive inhibitors of the cell surface receptors.[1,71,267,341] These are soluble receptors, as many cytokines and soluble cytokine receptors are generated by limited proteolysis of membrane-bound precursors. A TNFα protease inhibitor and other protease inhibitors have also been found to have the ability to modulate shedding.[374]

Signal Transduction

Receptor cross-linking by the TNF trimer is important for signal transduction. TNFs activate a sphingomyelinase, resulting in release of ceramide from sphingomyelin, which in turn activates a Mg^{2+}-dependent protein kinase. These include the three types of mitogen-activated protein kinase (extracellular signal-regulated kinase [ERK], jun amino-terminal kinase [JNK/p54], and p38) and a β-casein kinase. TNF-induced sphingomyelinase activity is secondary to the generation of DAG produced by a phosphorylcholine-specific phospholipase C (PC-PLC). Activation of phospholipase D and phospholipase A2 (PLA2) by TNFs has also been described. There is some evidence for G protein coupling of the TNFsRs to PLA2. Type I and type II receptors probably activate different cellular responses, and they may be coupled to distinct signal transduction pathways.[39,71,341,455]

Biological Actions

TNFs are mediators of both specific and nonspecific biological responses and an important link between immune and inflammatory reactions. Unfortunately, TNFs represent a two-edged sword in that severe catabolic effects (cachexia), tissue damage, and death can result from excessive uncontrolled production of these cytokines.[341,436,472,485]

TNFs were first known for their capacity to cause tumor necrosis in vitro, and they may also be the mediator of the occasional antitumor cytotoxicity observed after serious gram-negative infections. TNFα is the principal mediator of the host response to LPS of gram-negative bacteria and may play a role in multiple biological activities (antiviral, antiparasitic, lipolytic, glycogenolytic, and osteoclastic), some of them synergistically with IFNγ and IL-1.[1,152,436] TNFs also have widespread effects in inflammation and healing and are involved in granuloma formation, tissue necrosis, and fibrosis in many organ systems and, when produced in excess, vascular shock.[13,421,436]

TNFα is primarily responsible for a laboratory phenomenon known as the localized hemorrhagic "Shwartzman" reaction in which repeated injection of LPS into a solid tissue leads to hemorrhagic infarction. This occurs because LPS-induced TNFα secretion by macrophages can stimulate endothelial cells to release PGs, IL-6, and other mediators that cause coagulation, clotting, and obstruction of local blood supply.

TNFα, together with IFNγ, is also a powerful modulator of immune responses, mediating the induction of adhesion molecules, other cytokines (IL-1 and IL-6), and the activation of phagocytes. It is also a growth factor for fibroblasts and a major inducer of the acute phase response. TNFα influences the behavior of a wide variety of types of cells, and many of the activities of TNFα are shared with IL-1. In general, IL-1 is not toxic, and TNFα is a potent cytotoxic effector.

TNFβ manifests a wide range of similar parallel activities (inflammatory and antitumor immunity) affecting not only lymphocytes and neutrophils but also bone (resorption), endothelium (ability to enhance adhesion molecule expression), and neuronal cells.[341,436] However, several differences between TNFβ and TNFα are recognized, and the effect of TNFβ on endothelial cell growth is of particular interest. TNFβ appears to exert antiangiogenic effects on tumor blood vascular endothelial cells, with resulting hemorrhagic necrosis. In contrast, in wound healing, angiogenic effects such as those exerted by TNFα are thought to occur.[192,472]

The biological actions of TNFs are concentration dependent.[1] At low concentrations (approximately 1×10^{-9} mol/L), they act locally as paracrine and autocrine regulators of immunoinflammation—being rapidly released or secreted at sites of injury or infection. TNFα primes both neutrophils

and endothelial cells for adhesion and directs further the migration of leukocytes via chemotactic effects. TNFα-mediated proliferation of fibroblasts and endothelial cells is an important element of wound healing. In many of these activities, the effects of TNFα are amplified by IL-1, which acts synergistically with TNFα.[1,432,472] At high concentrations, TNFs (namely TNFα) act as an endocrine hormone with notorious systemic effects.

At low concentrations, the principal biological actions of TNFs locally include[1,152,432]:

1. Expression of adhesion molecules on endothelial cells (accumulation of leukocytes at local sites of inflammation, which is probably the physiologically most important local effect of TNFs)
2. Activation of inflammatory leukocytes to fight against microorganisms or tumor cells (especially potent for neutrophils, but also for eosinophils and mononuclear phagocytes)
3. Stimulation of cytokine synthesis (IL-1, IL-6, TNFα itself, CKs) by mononuclear phagocytes and other types of cells
4. Interferon-like protective effect against viruses

These effects of TNFs are critical for inflammatory responses to microbes and tumors. If inadequate quantities of TNFs are present, an organism may fail to suppress the infection. TNFβ is especially considered as a paracrine-type factor. It is cytostatic and cytotoxic for some tumor cell lines and causes necrosis of certain tumors in vivo. TNFβ also influences the function of B cells, T cells, connective tissue cells, and hematopoietic cells.

At moderate concentrations, TNFα enters the blood stream where it can act as an endocrine factor. The principal systemic actions of TNFs include[1,152]:

1. Acting as an endogenous pyrogen (shared with IL-1) and mediated by increased synthesis of PGs
2. Stimulation of secretion by mononuclear phagocytes and endothelial cells of IL-1 and IL-6 into the circulation
3. Increased synthesis of APPs by liver cells together with IL-1 and IL-6 (the spectrum of hepatocyte proteins induced by TNF is identical to that induced by IL-1 but differs from that induced by IL-6: IL-6 → fibrinogen, IL-1/TNF → serum amyloid protein)
4. Activation of the coagulation system
5. Suppression of bone marrow stem cell division
6. Cachexia, produced largely by TNF-induced appetite suppression; with IL-1, may also contribute to the cachectic state accompanying certain chronic diseases, such as tuberculosis and cancer

Because of activities similar to IL-1, TNFα is also considered an inflammatory cytokine. T-cell–derived IFNγ induces LPS-activated macrophages to make more TNFα. In fact, IFNγ enhances many of the effects of TNFα.

High quantities of TNFs are produced during gram-negative bacterial sepsis (serum concentration can exceed 10^{-7} mol/L), being a critical mediator in the complex cytokine network of septic shock (Figure 22-30). Several specific actions of TNFs may contribute to their lethal effects at extremely high concentrations[1]:

1. Reduction of tissue perfusion by depressing myocardial contractility (induction of nitric oxide synthase, producing NO, which inhibits myocardial contractility)
2. Reduction of blood pressure and tissue perfusion by relaxing vascular smooth muscle tone
3. Intravascular thrombosis (combination of endothelial and mononuclear phagocyte alterations, which promote coagulation, and activation of neutrophils—disseminated intravascular coagulation)
4. Severe metabolic disturbances, such as fall in blood glucose concentrations to levels that are incompatible with life

Many of the biological actions of TNF are augmented by IFNγ as previously mentioned (in some cells explained by IFNγ-stimulated increases in TNF receptor numbers). The

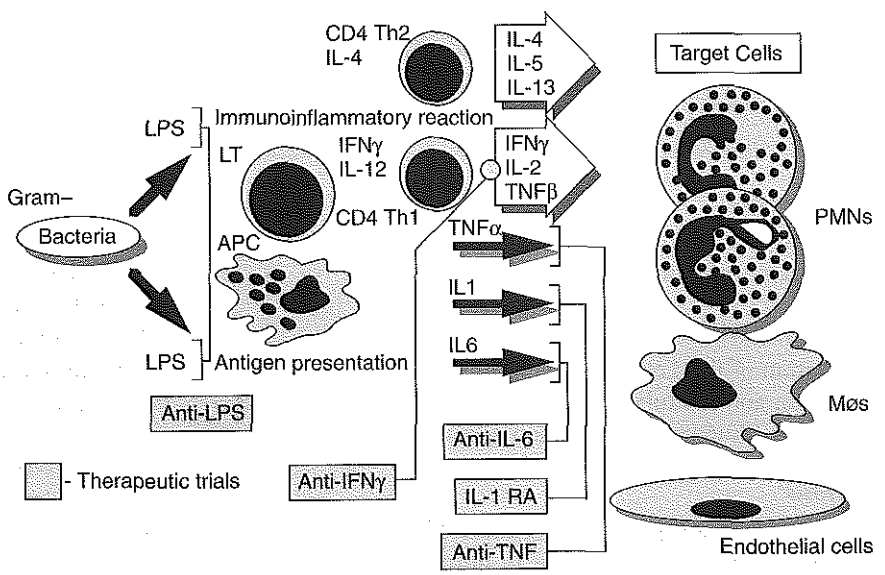

Figure 22-30 Illustration of a cytokine network in septic shock.

full significance of this interaction is not clear, but activated T cells often secrete TNF and IFNγ coordinately. Coordinate secretion of these two cytokines may provide a means of locally enhancing the actions of TNF without requiring concentrations that produce systemic toxicity.[225,351]

In addition, TNFs also have a number of other effects including (1) apoptosis, (2) adhesion and cellular trafficking, (3) angiogenesis, (4) myocyte proliferation, (5) fibrosis, (6) phagocytosis, (7) cytokine production and/or cellular activation, (8) leukocyte/macrophages function, (9) inflammation, and (10) tumor control.

Apoptosis

TNFα can induce apoptosis in many normal and transformed types of cells.[239] For example, activation of TNF receptors by TNFα or other members of the TNF superfamily causes an aggregation of receptors, which leads to the recruitment of various adaptor proteins that activate downstream kinases and proteases, including caspases. Mitochondria are important targets for TNF-initiated death signals. The subsequent release from mitochondria of reactive oxygen species, such as superoxide anion and cytochrome c oxidase and other factors that induce apoptosis, plays a pivotal part in TNF-induced cell death.[529]

TNFα and IL-1α also induce mannose receptors and apoptosis in glomerular mesangial but not in endothelial cells.[326] TNFα does not induce necrosis or apoptosis in EBV-positive or EBV-negative cell lines, regardless of the culture conditions of the cells or the presence or absence of cytokines.[408]

Adhesion and Cellular Trafficking

TNFα and IFNγ collectively and synergistically promote the inhibition of PECAM-1 (CD31) synthesis and leukocyte transmigration in endothelial cells, and human ICAM-1 expression can be up regulated by IFNγ or TNFα. Regulation of PECAM-1 expression on endothelial cells may modulate leukocyte trafficking, angiogenesis, and vascular permeability.[241,440,497] TNFα and IL-1 stimulate endothelial cell expression of CD54 (ICAM-1) and CD106 (VCAM-1). In addition to its ability to activate endothelial cell adhesion molecules, TNFα can induce directed migration of lymphocytes through collagen pads.[119,250]

Angiogenesis

TNFα is a pleiotropic cytokine that is also involved in angiogenesis and immunoregulation.[294]

Myocyte Proliferation

Activation of the TNFα p55 receptor induces myocyte proliferation and modulates agonist-evoked calcium transients in cultured human tracheal smooth muscle cells.[9]

Fibrosis

TNFα inhibits collagen synthesis and at high concentrations stimulates collagenase synthesis in fibroblasts.[553] Moreover, TNFα inhibits adherence and phagocytosis of collagen. These effects are mediated by a reduction in the strength of α2β1 integrin binding to collagen, possibly through tyrosine kinases in focal adhesions. At low concentrations of TNFα (10 ng/mL) that are found in the periphery of chronic inflammatory lesions, it has been suggested that inhibition of the collagen phagocytic pathway may contribute to fibrosis.[87]

Phagocytosis

Experimental data suggest that upregulation of complement receptor (CR3) and CR3-mediated phagocytosis are mechanisms by which TNFα and IFNγ stimulate nonphagocytic, nonbactericidal macrophage precursors to kill intracellular bacterial pathogens.[144]

Cytokine Production/Cellular Activation

TNFα and IFNγ mediate the induction of other cytokines (IL-1 and IL-6) and the activation of phagocytes.[472] It has been suggested that particle-induced expression of MIP-2 and cytokine-induced neutrophil chemoattractant CKs in the rat lung are mediated at least in part by production of TNFα.[145] TNF is involved in control of monocyte-mediated regulation of cytokine production by T cells. Preincubation of monocytes with rTNF enhanced their ability to induce IFNγ production, and TNF synthesis inhibitors decreased this induction. However, Th2 cells are stimulated in the relative absence of monocyte co-stimulatory signal(s), probably IL-6.[301] Concerning pain responsivity, TNFα produces dose-dependent hyperalgesia mediated via the induced release of IL-1β.[565]

Leukocytes/Macrophages Function

TNFα renders human neutrophils responsive to PF-4, a member of the CK superfamily. Over a broad range of concentrations, PF-4 by itself is unable to induce functional changes in PMN. However, neutrophils preincubated or coincubated with physiologically relevant concentrations of TNFα responded to PF-4 by the selective mobilization of the secondary granule marker lactoferrin but not of the primary granule marker elastase.[419] Stimulation of macrophages with IFNγ or TNFα shuts off the suppressive effect played by PGE2, which can explain how macrophage tumoricidal activity may be induced and maintained even in the presence of higher levels of PGE2.[598] The regulation of CD4 expression on macrophages and its role in immune cell interactions remain obscure. Experimental results show that LPS, TNFα, and IL-1β selectively down regulate CD4 expression in primary human macrophages and that decreased CD4 expression induced by LPS results from endogenous secretion of TNFα and IL-1β from the macrophages.[213]

Inflammation

TNF-stimulated gene 6 (TSG-6), encoding a 35 kDa secretory glycoprotein (TSG-6), is induced in fibroblasts, chondrocytes, synovial cells, and mononuclear cells by the

proinflammatory cytokines TNFα and IL-1. TSG-6 protein forms a stable complex with components of the serine protease inhibitor inter-α-inhibitor. The antiinflammatory effect of the TNF/IL-1–inducible TSG-6 protein, along with its ability to inhibit protease action (especially plasmin activity), suggests that TSG-6 production during inflammation is part of a negative feedback loop operating through the protease network.[458] IL-10 and IL-4 synergize with TNFα to induce IL-1RA production by human neutrophils and to favor an antiinflammatory condition.[345]

Tumor Control

The antitumor effects of TNFα are based on several distinct activities, including (1) direct cytotoxic effect on tumor cells but not on normal cells, (2) modification of the vasculature in such a manner that migration of lymphocytes into tumors is enhanced, and (3) stimulation of the immune response by activating cells that mediate antitumor immunity.[472]

Clinical Relevance

TNFs have been found to have clinical relevance in the disorders discussed below.

Infection/Septic Shock

TNFα is classically associated with septic shock and diverse infectious pathological conditions. It is involved in the development of a protective immune response in tuberculosis.[341] Measurable serum TNFα levels have been detected in 10.5% of children with pulmonary tuberculosis, all of whom belonged to the group with active disease.[28] Results suggest a protective role for TNFα in respiratory syncytial virus infection.[388] In patients with chronic hepatitis C during treatment with IFNα, elevated production of TNFα by PBMCs may be due to host response to the virus.[278] In HIV infection, TNFs and IL-6 stimulate viral replication.[15,436]

Autoimmune Diseases

TNFβ is considered to be an important mediator in a number of T-lymphocyte–mediated autoimmune diseases, such as type 1 diabetes.[472] Also, TNFs seem to play a pivotal role in certain autoimmune diseases, such as in the pathogenesis of RA, because transgenic mice constitutively overexpress TNF inflammatory arthritis but no systemic lupus erythematosus–like lesions. These findings in animals and humans suggest that the ambient level of TNF might have a hitherto underappreciated capacity to control the form in which autoimmunity is expressed as a specific syndrome or disease.[171]

Inflammatory/Allergic Diseases

TNFα is released by many inflammatory cells, including mast cells and eosinophils, and promotes mediator and cytokine secretion, adhesion molecule expression, and granulocyte migration. Consequently, TNFα is considered an important effector molecule and a pivotal mediator[57] in the pathogenesis of allergic respiratory reactions and in the acute stages of RA, being implicated in the cartilage damage.[76,88,286] Soluble receptors for TNF (sTNFR) are present at elevated concentrations in the synovial fluid of patients with RA. They are presumably released by cells of the synovial membrane, including the monocyte-derived synovial macrophages. Cytokines from the synovium, including IL-1 and TNFα, may stimulate sTNFR release. These observations help to explain why elevated levels of sTNFR in synovial fluid coexist with enhanced expression of cell-surface TNFR on synovial macrophages in RA.[52,247] DNA profiles (immunoprints) have been generated for patients suffering from early-onset pauciarticular chronic arthritis. The TNFα allele is not found in linkage disequilibrium with HLA-DRB1 and may be present on either chromosome 6. Thus a novel susceptibility factor probably within the TNFα/TNFβ gene region has been identified via linkage with the TNFα microsatellite allele.[156] Excessive synthesis and release of proinflammatory cytokines following trauma have been correlated with poor outcome in injured patients. TNFα appears to play a pivotal role as a trigger for the induction of systemic inflammation. Two naturally occurring inhibitors of TNFα, sTNFRs p55 and p75, have been characterized. Injured patients revealed increased plasma levels of both sTNFRs compared with healthy volunteers. Patients with severe injury revealed higher levels of sTNFRs on the day of admission than patients with minor trauma.[267]

Endometriosis

TNFα concentrations have been reported higher in the peritoneal fluid of women with endometriosis than in the peritoneal fluid of those without.[294] The mean concentration of IL-1β and TNFα has been found to be much higher in macrophage-conditioned media of patients with endometriosis without significant changes in peritoneal fluid.[269]

Cerebral Ischemia

Early increases in TNFα, IL-6, and IL-1β levels following transient cerebral ischemia suggest that regionally selective increases in cytokines may be involved in the pathophysiological changes in the hippocampus and striatum following transient cerebral ischemia.[452]

Acute Pancreatitis

As with sepsis, there is evidence that TNFα in particular may play a central role in acute pancreatitis and mediate the systemic sequelae of the disease. Analytical data have provided evidence that TNFα is a major contributor to the morbidity and mortality from acute pancreatitis.[227]

Nephropathies

Plasma levels of cytokines were measured in subjects hospitalized with nephropathia epidemica. Concentrations of TNFα, IL-6, and IL-10 were increased in all of these patients at admission. TNFα concentrations were still increased 1 week after onset of disease; levels of IL-6 and IL-10 normalized. Serum levels of the two soluble TNF receptors p55 and

p75 correlated with levels of the cytokine, indicating that receptor binding may be the reason for lack of bioactivity in vitro.[323]

Neurological Disorders

Two cytokines, TNFα and IFNγ, are involved in the progression of neurological disorders, such as multiple sclerosis and AIDS dementia complex, with an emphasis on cytokine effects on glial cells.[38]

Alcoholic Liver Disease

Increased serum and/or tissue TNF levels have been observed in alcoholic liver disease (see Chapter 47), and TNF has been postulated to play a role in ethanol-induced liver injury. It appears that both TNF and ethanol are capable of increasing manganese superoxide dismutase activity, presumably via enhanced oxidative stress.[417]

Transplant Rejection

TNFα has been implicated in the pathogenesis of both acute and chronic transplant rejection. Levels of this cytokine are known to vary in a normal population, leading to speculation that high responders may be at greater risk of rejection. Particular TNF region polymorphic markers have been associated with increased TNFα levels and a biallelic polymorphism has been identified in the TNFα promoter, which may contribute significantly to the interindividual variation in healthy persons. There is evidence for a new association between a polymorphic locus in the TNF gene region and increased production of TNFα in heart transplant recipients. No association was demonstrated for the promoter region polymorphism.[541]

Therapeutic Applications

Clinical trials have revealed that diseases that are related directly to excessive TNF production, such as septic shock, GVHD, and lupus nephritis, may be amenable to treatment either with anti-TNFα antibodies or with antiinflammatory agents that reduce TNF production, such as cyclosporin A and steroids.[343,472]

Neutralizing TNF in patients with RA by means of soluble TNF receptors or anti-TNF monoclonal antibodies has proven to be a powerful means of controlling disease activity. For example, the combination of neutralizing TNF with methotrexate has been found to improve the symptoms and signs of inflammation, physical function, and the quality of life and prevents radiographic evidence of progressive joint damage in a majority of patients with RA who have no response to methotrexate alone. Studies are in progress to obtain additional information regarding long-term safety of TNF blockade and its effects on disease progression as it was already evaluated with Crohn's disease.*

*References 18, 24, 171, 266, 314, 325, 505, 529, 593.

Infection/Septic Shock

A recombinant, soluble fusion protein that is a dimer of an extracellular portion of the human TNF receptor and the Fc portion of IgG1 (TNFR:Fc) binds and neutralizes TNFα and prevents death in animal models of bacteremia and endotoxemia. In patients with septic shock, treatment with the TNFR:Fc fusion protein does not reduce mortality, and higher doses appear to be associated with increased mortality.[166]

Inflammatory Diseases/Trauma

Anti-TNF therapies may have potential use in inflammatory arthritis. A review study of cytokine expression and regulation in rheumatoid joints has culminated in demonstrating that TNFα blockade markedly ameliorates arthritis. This defines an important therapeutic target for RA.[162] Experimental investigations have shown that a decrease in TNFα level or the inhibition of its activity is accompanied by reduced brain damage, affecting the development of cerebral edema and neurological dysfunction and hippocampal cell loss after closed head injury. These findings emphasize the role that TNFα plays in the inflammatory response following trauma.[483]

Tumors

TNFα has been shown to have limited success in the chemotherapy of some tumors, including melanomas (alone, or in combination with IFNγ), and it does not appear very promising for the treatment of human cancer. This is thought to be because of the observation that its toxicity in vivo precludes the administration of sufficient doses required to obtain blood levels high enough to cause cell death.[341,485] TNFα is one of the cytokines administered in immunotherapy of advanced neoplastic disease. Its action is exerted through immune endocrine and central nervous systems, and it might be possible that some side effects of human recombinant TNFα administration are connected with the decreasing cortisol level.[602] Because TNFα induces changes in integrin expression and adhesive properties, it can regulate adhesive mechanisms of tumor cells bearing adequate receptors, thus influencing lung-metastasis formation.[215]

Chemokines

Chemokines (CKs) are a group of low molecular weight cytokines that are identified on the basis of their ability to induce chemotaxis or chemokinesis in leukocytes (or in particular populations of leukocytes); in inflammation, the group is now divided into four subgroups on the basis of genetic, structural, and functional criteria. They function as regulators of the immune system and may also play roles in the circulatory and central nervous systems.[138]

CKs were discovered in the late 1980s as a result of advancements made in molecular biological techniques used to identify proteins. More than 50 have been identified but

their biological functions are not always known.[461] They are, however, thought to play key roles in the processes of inflammation and leukocyte migration, lymphocyte trafficking, and immune activation that precedes the wound healing process.[304,372,583]

General Characteristics

Chemokines is a condensation of the term "chemoattractant cytokines." Former names include (1) intercrines, (2) PF-4 superfamily of cytokines, or (3) SIS cytokines. CKs are now defined as a superfamily of low molecular weight proteins (8 to 10 kDa), regulating the motility and orientation of leukocytes. They are (1) proinflammatory mediators, (2) potent immunomodulators (lymphocyte activation and diversification), (3) biological modifiers of erythrocyte function, and (4) angiogenic factors. Their functional role indicates that CKs play a very important function as pathogenic mediators in several pathological conditions, including asthma, allergic diseases, infection, cancer, RA, sarcoidosis, pulmonary fibrosis, and atherosclerosis. In addition, they may also serve as targets for molecular mimicry in microbial invasion.

Classification

CKs are grouped into a CK superfamily that is further divided into four families (CXC, CC, C, and CX_3C) according to their amino acid sequence around one conserved motif that includes four cysteines (Box 22-6).* These four families also correlate with separate gene clusters (in humans, the CXC family is located on chromosome 4q12-21, the CC on 17q11-32, C on 1, and CX_3C on 16q13). The classical members of these families are summarized in Table 22-7. The respective acronyms, main function, and new nomenclature are listed in Table 22-8 and Figure 22-31. Despite the large size of this superfamily, there are elements (like the NAP-4 and P500) that are not easily integrable inside the previously described families, because they lack some cysteines in the classical four-cysteine conformation.

As indicated in Table 22-8, most of CXC CKs are attractants for PMNs (neutrophils, eosinophils, and basophils) but not for monocytes. Most of the ELR-CXC molecules are potent neutrophil chemoattractants and share the CXC CK

BOX 22-6 Chemokine Families

CXC (also known as α family): Contains one amino acid (X) *between the first two cysteines*
- CXC subfamilies (according to the sequence of amino terminal region)
- ELR-CXC (glutamic acid-leucine-arginine-cysteine-amino acid X-cysteine)
- *No ELR preceding CXC*

CC (also called β family): Absence of one amino acid between the first two cysteines

C (also called γ family): Lack of the first and third cysteines (one instead of two cysteines in their N-terminus)

CX_3C (also called δ family): Novel arrangement of cysteine residues (CysXaaXaaXaaCys), followed by an extended mucinlike stalk, a transmembrane domain, and an intracellular domain

receptor. In contrast, those without the ELR motif show different chemotactic functional capacities and do not seem to link themselves to the same receptor. CC CKs attract mononuclear cells (monocytes and lymphocytes) but not neutrophils. C CKs attract specific kinds of leukocytes (lymphocytes) but not neutrophils and monocytes. Exceptions to these general rules include CXC CKs IL-8, IP-10, and melanoma growth stimulatory protein (MGSA), which are chemotactic to T cells, and CC CKs MCP-1, MCP-3, RANTES gene, and MIP-1α, which are chemotactic to basophils.[461,545]

Functionally, CKs are categorized as "homeostatic" or "inflammatory." Homeostatic CKs are produced and secreted constitutively and are generally involved in lymphocyte trafficking and immune surveillance. Inflammatory CKs are only produced by cells during infection or following a proinflammatory stimulus; they prompt the migration of leukocytes to an injured or infected site and can also activate cells to raise an immune response.[304,583]

In general, the CKs are remarkably diverse, in terms of both individual proteins and their production by blood and tissue cells, and some cannot be assigned unambiguously to either one of the two functional categories. These are referred to as "dual-function" CKs and generally participate in immune defense functions, such as those that are up regulated under inflammatory conditions and target noneffector leukocytes, including precursor and resting mature leukocytes, at sites of leukocyte development and immune surveillance. Many dual-function CKs are highly selective for lymphocytes and have a role in T-cell development in the thymus and in T-cell recruitment to inflammatory sites. In contrast to homeostatic and dual-function CKs, inflammatory CKs have broad receptor selectivities.[372]

Molecular Structure

The three-dimensional structures have been elucidated for many CXC and CC CKs. As expected from the high degree of sequence identity of these molecules, the structures of all the monomers are very similar. However, the quaternary structures of the CXC and CC CKs are distinct and the dimer interface is formed by a totally different group of residues. The three-dimensional conformation is globular for IL-8 (CXC CK) and elongated and cylindrical for MIP-1β (CC CK). PF-4 (a CXC CK) is a tetramer composed of a dimer of IL-8–type dimers. The differences in the quaternary structure provide an explanation for the lack of receptor cross-binding between CXC and CC CKs.[545] However, although dimerization and aggregation is often observed, the CKs function as monomers, and the critical receptor-binding regions are in the NH2-terminal 20 residues of the protein.[91,195]

Biological Function

CKs have many important biological functions, several of which are summarized below.

Inflammation

Chemoattractant properties are the major biological effect of CKs. Their receptors are G protein–coupled receptors that form a family of structurally and functionally related proteins. CKs are induced in cells and tissue in response to proinflammatory cytokines. They are produced by a large diversity of cells (Figure 22-32). The CK superfamily, with the exception of RANTES, β-TG, HCC-1, and PF-4, is not expressed in resting cells but is rapidly induced in response to various inflammatory and mitogenic stimuli. Probably all CKs have some activities that are unique and many that are

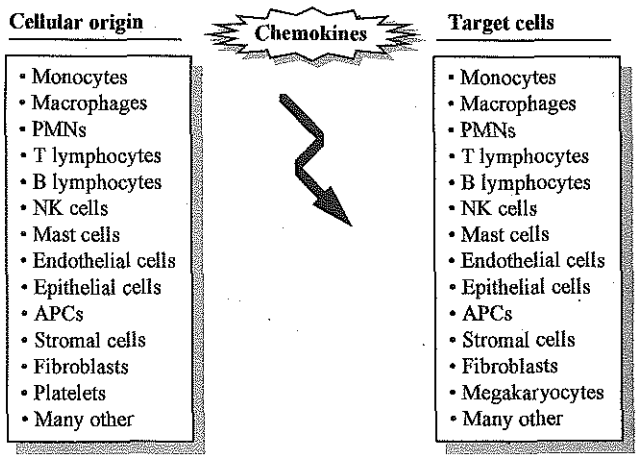

Figure 22-32 Cellular origin and principal target cells of chemokines.

overlapping that include (1) cellular migration, (2) calcium mobilization, (3) cellular adhesion, and (4) signal transduction. In addition, CKs are implicated as major participants in (1) acute and chronic inflammatory reactions, (2) inhibition of hematopoiesis, (3) modulation of angiogenesis, and (4) fibroplasia. They act on T lymphocytes, presumably influencing the recruitment of immunocompetent cells to immunoinflammatory sites. Although there is no evidence that CKs play a role in the induction of immune reactions, they promote the effector limb of immunity. CKs may also contribute to the normal homing and distribution of leukocytes. Although CKs obviously have major differentiative effects on the functions of target cells, the possibility that they act as co-stimulants of cell growth is also being studied. Finally, CKs are attractive targets for the development of new therapeutic agents. For example, inhibition of their activities may be an effective antiinflammatory strategy; promoting their activity might enhance wound healing and tissue repair.[519,572]

Chemokines in Leukocyte Trafficking

CKs are thought to be centrally involved in leukocyte trafficking and not limited to attraction of monocytes by the CC family and neutrophils by the CXC family.[399] Other functions of the CKs include expression of adhesion molecules, especially for the lymphocytes in both the migratory response and maturation and proliferation.[461] The selective chemoattractant qualities shown by CKs explain the directed migration of each kind of leukocyte or even of subtypes of these cells (as T and B lymphocytes, perhaps even Th1 and Th2). Several studies have shown that CC CKs attract T lymphocytes and that CD45R0, memory-phenotype cells are considered to be the main responders. The results, however, have often been contradictory, and the role of lymphocyte activation and proliferation is still unclear. The CC CKs MCP-2, MCP-3, RANTES, MIP-1α, MIP-1β, and MCP-1 induce significant, dose-dependent transendothelial chemotaxis of CD3 T lymphocytes. In contrast, the CXC CKs IL-8 and IP-10 fail to induce transendothelial chemotaxis of CD3 T lymphocytes or T-lymphocyte subsets. RANTES, MIP-1α, and MIP-1β induce significant transendothelial chemotaxis of CD4, CD8, and CD45R0 T-lymphocyte subsets. Phenotyping of mononuclear cells that underwent transendothelial migration to MCP-2, MCP-3, RANTES, or MIP-1α shows both monocytes and activated (CD26 high) memory-type (CD45R0) T cells. Both CD4 and CD8 T lymphocytes were recruited but not NK cells or many B cells. In fact, MCP-2 was the only CC CK tested that attracted a substancial number of naive type (CD45RA) T lymphocytes. In the absence of endothelium, IL-8 but not IP-10 promoted modest but significant chemotaxis of CD3 T cells.[329,447]

CKs also play a role in leukocyte trafficking during ovarian function. For example, CKs are expressed and leukocytes accumulate within the ovulatory follicle and the corpus luteum. Hormonal and embryonic regulation of CKs are thought to be responsible.[137,532]

For CKs to act in vivo, they require a solid phase in which normal conditions of blood flow would be unable to wash away the chemoattractant gradient. In this manner, CKs secreted by each cell trafficking through a vessel are sequestered and maintained by stable components of the extracellular matrix, such as proteoglycans.[461] This model of CK action in leukocyte migration is summarized in Figure 22-33.

Hematopoietic Function

Several CKs have marked activity in hematopoietic precursor cell cycling regulation and differentiation, MSGA/GRO acts as a growth factor, and IL-8 is a potent angiogenic factor (possibly shared by other ELR-CXC CKs). Although this prohematopoietic capacity is important, some are suppressive (such as IP-10 and MIP-1α), inhibiting the action of growth factors in hematopoietic cells.[16] However, PF-4 presents the most fascinating spectrum of biological activities, including inhibition of tumor growth, megakaryopoiesis, reversal of immunosuppression, and bactericidal capacity. Curiously, MIP-1α and MIP-1β, despite their structural similarities, show diverging signaling capacities. Depending on the MIP-1 subtype and its NH2-terminal processing, one or more of the CC CK receptors CCR1, CCR2, CCR3, and CCR5 are recognized.[142] Since both human MIP-1α subtypes (LD78α and LD78β) and MIP-1β signal through CCR5, the major co-receptor for M-tropic HIV-1 strains, these CKs are capable of inhibiting HIV-1 infection in susceptible cells.[361]

Proliferation of B-Cell Progenitors

SDF-1 stimulates proliferation of B-cell progenitors in vitro and is constitutively expressed in bone marrow–derived stromal cells.[381]

Leukocyte Activation/Inflammation

The biological role of PF-4 in the regulation of neutrophil function is different from that of IL-8 and other CKs. It

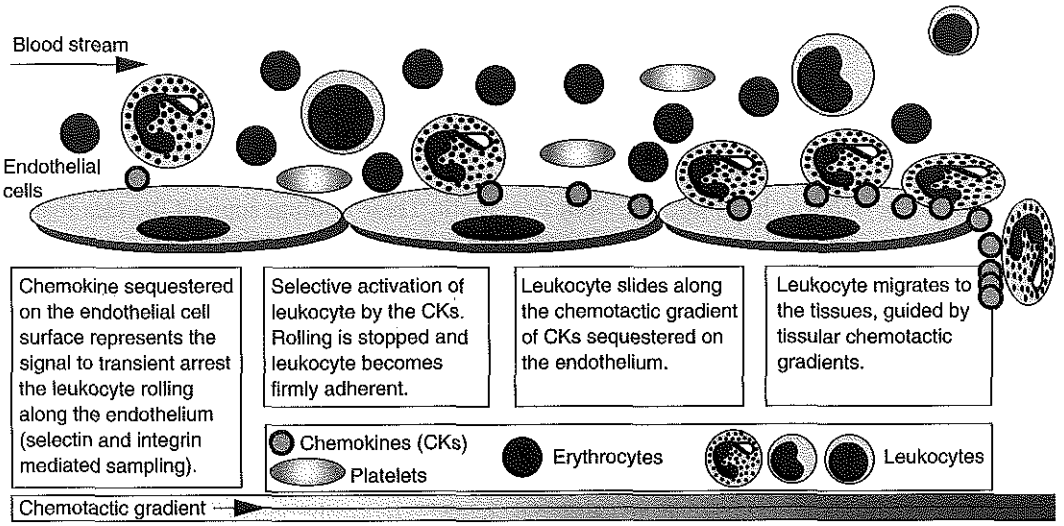

Figure 22-33 *Function of chemokines in leukocyte migration.*

is limited to the selective mobilization of the secondary granule marker lactoferrin but not of the primary granule marker elastase from neutrophils treated with TNFα.[419] The β-CK family contains members that stimulate basophils and eosinophils to secrete proinflammatory substances, such as histamine or eosinophil cationic protein. MCAF/MCP-1, MCP-2, MCP-3, RANTES, and MIP-1α all attract and stimulate basophils; MCP-1 and MCP-3 are the most potent. RANTES, MCP-3, and to a lesser degree MIP-1α are chemotactic factors and activators of eosinophils. These substances may have particular importance as mediators of allergic inflammation, particularly the late phase component of the allergic response.[254] It is surprising that RANTES, MCP-1, MCP-2, MCP-3, MIP-1α, and MIP-1β have no effect on mast cell activation, showing evidence for the differences between human mast cells and basophils regarding cytokine-dependent activation.[209]

During organogenesis, immunosurveillance, and inflammation, CKs selectively recruit leukocytes by activating seven transmembrane-spanning receptors. It has been suggested that an important component of this process is the formation of a haptotactic gradient by immobilization of CKs on cell surface glycosaminoglycans (GAGs). Each tissue produces specific repertoires of GAGs, some of which are known to bind and regulate CK activity. Several lines of evidence point to the importance of one particular GAG, heparan sulfate (HS), in promoting CK activity.[331,425]

Lymphocyte Recruitment and Activation

The β-CKs, MIP-1α, and MIP-1β; RANTES; and MCP-1 have been found in vitro capable of directly co-stimulating purified human T-cell and human T-cell clone proliferation and IL-2 production in the presence of anti-CD3 but not phorbol esters. CK treatment of human T cells in vitro increases the level of cell surface CD25 and soluble CD25. In addition, these CKs enhance both antigen and alloantigen-specific T cells and T-cell clone proliferation. This activity was further augmented in the presence of the CD28 ligand, B7-1. Together, these results suggest that CKs not only play an important role in lymphocyte recruitment to inflammatory sites, but also participate in T-cell activation.[520] CD8 T-lymphocyte accumulation is strongly enhanced by MIP-1α, and RANTES may have a physiological role in T-lymphocyte recirculation.[521] RANTES is a CK whose gene is expressed immediately after stimulation of several types of cells but up regulated late (3 to 5 days) after activation in normal T lymphocytes. This is dependent on two cis-acting elements in the human RANTES promoter that act in T lymphocytes. One is activated within the first 24 hours after T-cell activation, and the second site is up regulated later, between days 3 and 5. These data provide an explanation for the immediate early expression of RANTES in some types of cells and identify apparently novel factors contributing to late RANTES transcription in T cells.[403] MIG is a CK of the CXC subfamily that is inducible in macrophages and in other cells in response to IFNγ. Human MIG induces the transient elevation of $[Ca^{2+}]$ in TIL and human peripheral activated lymphocytes. No responses have been seen in human neutrophils, monocytes, or transformed lymphoblastoid cell lines. It was concluded that human MIG plays a role in T-cell trafficking and perhaps in other aspects of the physiology of activated T cells.[317] Evidence indicates that MCP-1, MCP-2, and MCP-3 are active on NK cells.[491]

Lymphocyte trafficking through internal organs is thought to be controlled by rather general, tissue-nonspecific, "inflammatory" adhesion molecules and CK receptors, unlike lymphocyte homing to epithelial surfaces. The so-called homing subsets of effector and memory T cells with distinct tissue tropism have been identified: the integrin and

CK receptor CCR9 target T cells to the small intestinal mucosa. By contrast, skin-homing T cells display selectin ligands in combination with CCR4 and/or CCR10. It remains to be determined whether T cells expressing skin-homing markers are exclusively homing to skin or also to other tissue. Distinct homing subsets for other organs, such as the lung, liver, brain, or kidney, have not yet been reported.[147]

Platelet Activation

Tethering of the monocytes by P-selection is required for their activation by RANTES. This suggests that activated platelets regulate CK secretion by monocytes in inflammatory lesions.[575] Platelets express mRNAs for the following CKs: CTAP-III, ENA-78, RANTES, and MCP-3. Platelets also express mRNAs for IL-8RA and a novel CK receptor CCR4. These results suggest that CKs may not only play an important role in platelet activation, but also influence the nature of the leukocyte infiltrate to sites of inflammation and infection.[424]

Immune Response

Induction of oral tolerance was prevented by the administration of anti-MCP-1. These results indicate that CKs play an important role in the induction of oral tolerance.[258] There is evidence that both CXC and CC CKs are integral components of antibacterial host defense. Specifically, in vitro studies indicate that CXC CKs (IL-8 and MIP-2) and the CC CK MIP-1α augment the ability of PMNs and alveolar macrophages, respectively, to phagocytose and kill *E. coli*. In addition, the intratracheal instillation of *Klebsiella pneumoniae* in mice results in time-dependent production of MIP-2 and MIP-1α. Inhibition of MIP-2 bioactivity in vivo results in decreases in lung PMN influx, impaired bacterial clearance, and early mortality.[495]

MIP-1α, MIP-1β, RANTES, and ATAC are not only chemoattractants but also co-activators of macrophages, so together with IFNγ they constitute a group of cytokines that act together as a functional unit, which is used by NK cells in the innate phase and in the antigen-specific phase of the immune defense, thus bridging the two components of a Th1 immune reaction.[139] T cells express a large variety of CK receptors and respond to an impressive number of CKs. In most cases, regulation of CK receptor expression depends upon the phenotype and consequent functional properties of the T cells (namely Th1 and Th2 phenotypes).[445,583]

Angiogenic Activity

The CXC CK family displays disparate angiogenic activity, depending on the presence or absence of the ELR motif (a NH2-terminal motif previously found to be important in ligand/receptor interactions). CXC CKs containing the ELR motif, such as IL-8, are potent angiogenic factors, inducing both in vitro endothelial chemotaxis and in vivo corneal neovascularization. In contrast, CXC CKs lacking the ELR motif (PF-4, IP-10, and MIG) not only fail to induce significant in vitro endothelial cell chemotaxis or in vivo corneal neovascularization, but are found to be potent angiostatic factors in the presence of CXC CKs containing the ELR motif. These findings support the idea that the net biological balance in the magnitude of expression of angiogenic and angiostatic CXC CKs at either the site of wound repair or during tumorigenesis may be important in the regulation of net angiogenesis.[44,446,500,502]

Cell Adhesion

The CKs RANTES, MCP-1, and to a lesser extent MIP-1α, MIP-1β, and IL-8 are able to induce uropod formation and ICAM-3 redistribution in T lymphoblasts adhered to ICAM-1 or VCAM-1. A similar CK-mediated effect has been observed during T cells binding to the binding sites for the integrins VLA-4 and VLA-5. The uropod structure concentrates the ICAM-3 adhesion molecule (a ligand for LFA-1) and emerges to the outer milieu from the area of contact between lymphocyte and protein ligands. In addition, this study demonstrates that other adhesion molecules, such as ICAM-1, CD43, and CD44, also redistribute to the lymphocyte uropod upon RANTES stimulation, whereas a wide number of other cell-surface receptors do not redistribute. CKs display a selective effect among different T-cell subsets; MIP-1β had more potent action on CD8 T cells and TIL, whereas RANTES and MIP-1α targeted selectively CD4 T cells. These results demonstrate that uropod formation and adhesion receptor redistribution are novel functions mediated by CKs. This phenomenon may represent a mechanism that significantly contributes to the recruitment of circulating leukocytes to inflammatory foci.[123]

The molecular basis of cancer metastasis suggests that metastatic cancer cells simply use signals that normally control leukocyte transport focused on CKs and there is some evidence to support that CXC CK receptor 4 (CXCR4) and its ligand CXC CK ligand 12 (CXCL12) together govern the pattern of breast cancer metastasis.[378]

Clinical Relevance

CKs have important roles in a large diversity of human pathological conditions, namely in HIV infection; transplant rejection; rheumatic, allergic, and autoimmune diseases; cancer; atherosclerosis; and general immunoinflammatory processes (systemic or related with central nervous system), and are expected as promising targets for new molecular therapies.*

*References 54, 59, 69, 214, 222, 226, 265, 282, 327, 328, 376, 378, 500, 506, 510, 554, 558.

AIDS/HIV Infection

CKs are promising molecules for therapy in AIDS.[524] This hypothesis is based on two observations: (1) increased levels of MIP-1α, MIP-1β, and RANTES in long-term nonprogressors (individuals who do not show evidence of disease from HIV, even a long time after being infected) and (2) the observation that CCR5 plays a critical role in HIV capacity to infect CD4 cells. In addition, MIP-1α and MIP-1β are induced in human monocyte cultures following infection with the HIV-1. Induction depends on productive viral infection: Not only does the kinetics of MIP-1 peptide induction closely follow that of viral replication, but monocyte cultures inoculated with heat-inactivated virus or infected in the presence of 3′-azido-3′-deoxythymidine (AZT) failed to produce these β-CK peptides.[464] The RANTES is a T-cell–expressed, proinflammatory CK that has been implicated as a suppressive agent of HIV replication.[12,387] However, some investigators have argued against the CKs being clinically relevant for AIDS therapy.[93,141,456]

Several CK receptors have been implicated in HIV entry in various experimental systems, with CCR5 being the most important mediator of R5 HIV entry because of its role in transmission early in the disease. CCR5 is now a highly validated target for the treatment of HIV-1 infection. In vitro, cells cannot become infected with certain strains of HIV-1, designated R5-tropic, if they do not express CCR5 in conjunction with the primary receptor CD4. Natural and synthetic ligands for CCR5, such as RANTES, AOP-RANTES, MIP-1α, MIP-1β, Met-RANTES, andLD78β (MIP-1α isoform), protect against R5 virus infection in vitro. This extends to in vivo where it has been observed that individuals with high levels of MIP-1β have decreased risk of HIV progression.[265]

Transplant Rejection/Kidney Pathological Conditions

CKs are thought to play a role in directing inflammatory cells to graft sites and initiate rejection.[434] For example, in murine allogeneic skin grafts, two general patterns of CK gene expression have been observed. In the first, CK genes—including MIP-1α, MIP-1β, JE, and KC—are observed at peak levels 3 days posttransplant. In the second pattern, CKs such as RANTES and IP-10 are expressed at high levels 3 to 4 days before rejection of the allografts is complete. These two patterns of chemoattractant cytokine gene expression may be representative of the early inflammatory and the late T-cell–mediated phases of the allograft rejection process, respectively.[284] CKs are also involved in mediating renal pathological conditions and proteinuria. IL-8, RANTES, and MCP have been extensively studied in the kidney.[572]

Allergic Diseases

Both CXC and CC CKs have been found to be expressed in pulmonary-derived mast cells, suggesting an important contribution to leukocyte responses in the allergic airway.[334,399] This CK expression contrasts with the previously mentioned observation that RANTES, MCP-1, MCP-2, MCP-3, MIP-1α, and MIP-1β have no action on mast cell activation.[209]

Studies in both animals and humans have demonstrated a positive correlation between the inflammatory state of the airways and the severity of airway hyperreactivity. However, because the type and etiology of this inflammation and the extent and consequences of the inflammatory process vary between different diseases exhibiting airway hyperreactivity, the direct contribution of individual types of cells or CKs to airway hyperreactivity requires further investigation.[54]

Autoimmune Diseases

Production in the central nervous system of MIP-1α plays an important role in directing the chemoattraction of mononuclear inflammatory cells in the T-cell–mediated experimental autoimmune encephalomyelitis.[259]

Persons with type 1 diabetes have increased peripheral blood mononuclear cell expression of CK receptors CXCR4 (naive T cells), CCR5 and CXCR3 (Th1-associated), CCR3 and CCR4 (Th2-associated) and serum CK levels of MCP-1, MIP-1α, MIP-1β, and RANTES. A reduced expression of the Th1-associated CK receptors CCR5 and CXCR3 in type 1 diabetes patients and a genetic association involving a single-base polymorphism in CCR2 has been suggested.[20]

Rheumatic Diseases

MIP-1β has been identified as a unique CK that is increased in the synovial fluid from osteoarthritic patients but not in the synovial fluid of RA patients. This observation indicates that MIP-1β may play a role in the ingress of monocytes into the osteoarthritic joint.[283]

In addition, several studies have emphasized the role and therapeutic approaches of CKs and CK receptors in RA and inflamed synovia.[328,412,508,517]

Hemolytic Diseases/Transfusion

PF-4, β-thromboglobulin, and RANTES are released from platelets during storage and accumulated over time in the platelet concentrates. These CKs might play a causative role in nonhemolytic transfusion reactions because of their inflammatory potential, but the clinical effects of the transfusion of platelet concentrates with high CK contents are still being investigated.[67]

Inflammatory Processes[204]

MCP-1 and RANTES are thought to contribute to the recruitment and activation of leukocytes in mucosa from patients with inflammatory bowel disease, suggesting that these CKs play a role in the pathogenesis of mucosal inflammation. Furthermore, the expression of the MCP-1 gene in vessel-associated cells may indicate its involvement in mechanisms regulating the adhesion of blood monocytes to

endothelial cells.[352] Eotaxin and CCR-3 may be host factors highly specialized for eosinophil recruitment in inflammation and may be good targets for the development of selective drugs for inflammatory diseases in which eosinophils contribute to pathogenesis, such as asthma.[280,428]

Chemokine Receptors (CKRs)

Several kinds of structures able to receive functional signals of CK are known. The most important ones can be formed into the following categories: (1) specific receptors, (2) shared receptors, (3) promiscuous receptors, (4) virally encoded receptors, and (5) orphan receptors.[461,545]

The attempt to define CK receptors has been based primarily on four different methods: direct binding, signal transduction, molecular cloning, and structure function. All of these have advantages and handicaps related to the intrinsic methodology, but the complexity of receptor characterization derives also from the biological model, including the number of CKs simultaneously used (for example, CC, CKR-1 binds MIP-1α, RANTES, MIP-1β, and MCP-1 and has been reported as an MIP-1α/RANTES receptor).[526] Among the CKRs, the IL-8 receptors were the first to be studied at the molecular level. Now, several CK receptors have been cloned and characterized and all found to be members of the G-protein coupled receptor superfamily (GPCR). Rhodopsin is the typical GPCR, although other molecules exist, namely calcitonin-like, metabotropic, pheromone-like, and cAMP-like. Using gene mapping studies, receptors with the highest sequence similarity have been found to be closely linked on human chromosomes. This close genetic association suggests a functional relationship as well.[431] These receptors are integral membrane glycoproteins with a structure composed of seven helices snaking through the cell membrane with the N-terminus on the extracellular face. CKRs are coupled to regulatory GTP-binding proteins, leading to signal transduction.[545]

Specific Receptors

Specific receptors bind only one CK. In practice, it is difficult to define the specificity of a receptor for CKs.[3] However, some of them, such as the IL-8 receptor A (IL-8RA) and the MCP-1 receptor (MCP-1R), have been found to be specific.

Shared Receptors

Shared receptors are defined as able to bind more than one CK; this concept is only valid inside each CK family. For example CCL20, alternatively named liver and activation-regulated CK (LARC), macrophage inflammatory protein-3α (MIP-3α) or Exodus-1, is the only CK known to interact with CC CK receptor 6 (CCR6), a property shared with the antimicrobial β-defensins. The ligand-receptor pair CCL20-CCR6 is responsible for the chemoattraction of immature dendritic cells, effector/memory T cells, and B cells and plays a role at skin and mucosal surfaces under homeostatic and inflammatory conditions and in pathological conditions, including cancer and RA.[467]

CXC Chemokine Receptors (CXC CKRs or CXCRs). The CXC CKs have been found to have six human receptors: CXCR1, CXCR2, CXCR3, CXCR4, CXCR5, and CXCR6.*

CC Chemokine Receptors (CC CKRs, or CCRs). The CC CKs have at least 10 receptors: CCR1, CCR2, CCR3, CCR4, CCR5, CCR6, CCR7, CCR8, CCR9, and CCR10.† CC CKs do not bind to the CXC receptors because the three-dimensional structure of the ligand differs in a region between the two families and by a modification of the amino terminus. This suggests a two-site model for receptor activation and for selectivity between CC and CXC CKs, with an initial receptor contact provided by the main body of the CK and activation provided by the amino terminal region.[570] The different cellular expression of CC CKRs enables selective biological actions (e.g., monocyte responses to MCP-3 that could be mediated by both CCR2 and CCR1), whereas eosinophil responses to MCP-3 could be mediated by CCR1.[96]

Promiscuous Receptors

By definition, promiscuous receptors bind several CKs outside their family (CXC or CC). The most important is the Duffy antigen receptor complex (DARC), or Duffy antigen receptor for CKs, that is present on several cellular types, especially on erythrocytes (thus it also has been called erythrocyte CK receptor). In a 1995 study, Szabo and coworkers[507] suggest that the promiscuous nature of DARC is limited because C and non–ELR-CXC CKs do not bind to it. This also occurs inside the CC family with MIP-1α and MIP-1β, contrasting with RANTES and MCP-1, that bind to the Duffy antigen.[3,223] This demonstrates that the ELR motif is not crucial for CK binding to DARC. The presence of this receptor must be seen mostly as a regulatory mechanism of the CK's biological function with a clear "sink" role and a "drain" capacity clearing excess CK from the circulation‡ and maintaining the sensitivity of blood leukocytes to CK gradient generated by local inflammatory foci but also allowing the action of CK on cells without other more specific receptors (such as IL-8RA and IL-8RB). It is curious, for instance, that lymphocytes appear to vary the level of DARC expression according to their state of activation and differentiation.[293,461] DARC is also a receptor for the malaria parasite *Plasmodium vivax* but the parasite ligand has no similarity to the CKs.[1,341] However, the lack of DARC expression

*References 3, 223, 229, 376, 338, 401, 476, 545, 558, 570.
†References 95, 141, 220, 296, 338, 369, 376, 401, 402, 422, 430, 456, 545, 558.
‡Although the normal circulating levels of IL-8 are in the picomole range, they can be as high as 8 nmol/L in sera of patients with sepsis or acute respiratory distress syndrome, implying the "drain" of surplus IL-8 molecules.

(Duffy-negative phenotype) has not yet been correlated with any kind of disease susceptibility, but only with the advantage to individuals exposed to *P. vivax*.

DARC is mapped in human chromosome 1q21-25 and is expressed in human erythrocytes and on endothelial cells lining postcapillary venules, brain, kidney, spleen, lungs, and thymus. The expression of DARC by subsets of endothelial cells and neurons in discrete anatomical sites in the brain suggests that this enigmatic receptor may have multiple roles in normal and pathological physiology. Conservation of this promiscuous CK-binding activity is evident from the similarity in nucleotide sequence of DARC homologues from multiple species and the high-affinity binding of human CKs to murine and avian erythrocytes. The hierarchical expression of DARC in neurons in the cerebellum suggests that CKs may play an important role in the modulation of neuronal activity by glial cells.[223,224]

The platelet activating factor receptor as a GPCR (rhodopsin family) is possibly also a promiscuous receptor for CKs. The same can be considered for the chemoattractant receptors, complement 5 anaphylatoxin receptor, and FPR/FMLPR (N-formyl peptide receptor).

Virally Encoded Receptors

Virally encoded receptors (homologues of the native CK receptors) represent the possible subversion of these receptors by viruses and the two known to date are of shared type. The first is the human cytomegalovirus open reading frame US28; it is a CC-shared receptor (it binds MIP-1α, MIP-1β, MCP-1, and RANTES). The second is the Herpesvirus saimiri (HVS) ECRF3; it is a CXC-shared receptor (it is activated by the same CKs that bind to IL-8 RB but with different capacity; for IL-8 RB, the hierarchy is IL-8 greater than GROα = NAP-2, and for ECRF3 is GROα greater than NAP-2 greater than IL-8). The biological significance of these receptors is not well understood and is the subject of intensive research. It is already clear that a few microorganisms use the plasticity of genomes to immunomodulate the host defense. ECRF3 is functionally active (in contrast with US28, which lacks a known signaling activity), and it may sensitize HVS-infected T lymphocytes (without IL-8 RB) to CXC CKs as a way to establish cytosolic ideal conditions for replication.[3] This may be very important in clinical practice, mainly for immunocompromised hosts.[218,338]

Orphan Receptors

Several DNAs have been cloned that have homology to the already known members of the CK-receptor family, although they have not yet shown functional significance. The principal orphan receptors are CMK-BRL-1 (CK β-receptor-like-1), BLR-1/MDR-15 (Burkitt's lymphoma receptor-1/monocyte-derived receptor-15), V28, and EBI1.[545]

Functional Signaling

The biological effects of CKs are mediated by complex components requiring seven transmembrane, G-protein-linked receptors on the surface of target cells. The complexities of interactions between CKs and cytoplasmic components of target cells are summarized in Figure 22-34.[461]

Experimental research regarding the types of G proteins coupled to CC CKRs suggests that MCP-1 and RANTES receptors are promiscuously coupled to multiple G proteins in IL-2-activated NK-cell membranes and that this coupling is different from MIP-1α receptors, which seem to be coupled to G(s), G(o), and G(z) but not to G(i).[5] The CCR1 and CCR2 can reconstitute ligand-induced accumulation of inositol phosphates with PLC β2 in a pertussis toxin-sensitive manner, presumably through Gβγ released from the G(i) proteins.[563] However, these receptors demonstrate different specificity in coupling to the α subunits of the G(q) class. The results suggest that some of the CC CK receptors, unlike the CXC CK receptors, discriminate against Gα16, a hematopoietic-specific Gα subunit. The intriguing specificity in coupling of the G(q) class of G proteins implies

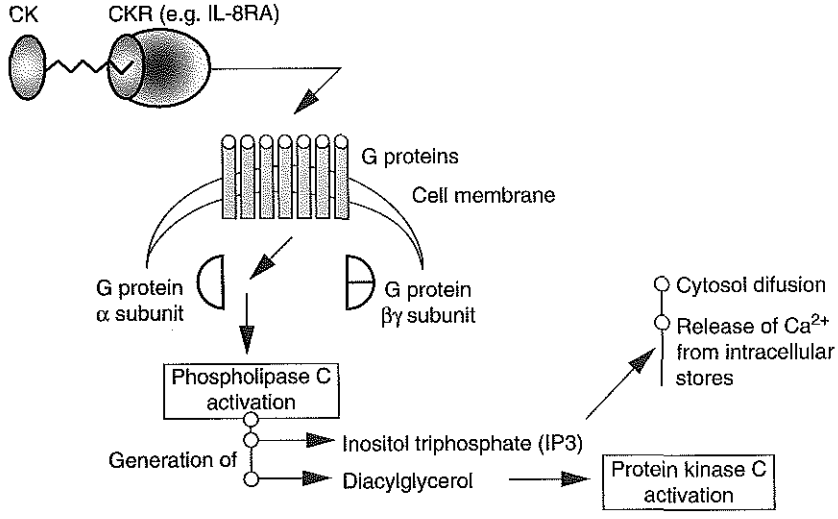

Figure 22-34 Signal transduction of chemokines.

that the CKs may be involved in some distinct functions in vivo.[290]

Regulation of Chemokine Activity

The control of CK activity probably depends on several mechanisms, such as the presence of a clearance receptor in red blood cells, such as DARC, and anti-CK antibodies in the circulation.[461] Also the genetic expression of some CKs (such as IL-8) seems to be tightly regulated, leading to a short half-life of mRNA expression.[341] Oxidized low-density lipoprotein (LDL) has been found to greatly potentiate the expression of the KC (murine equivalent to GROα) CK gene in LPS-stimulated macrophages, whereas levels of IP-10 mRNA are altered in the opposite fashion. These effects on KC gene transcription are in marked contrast to previous reports demonstrating inhibitory effects of oxidized LDL on LPS-induced M CK expression. Thus extensively oxidized LDL acts on the transcriptional control process in macrophages in both a positive and negative fashion on separate members of the same gene family.[208] These experimental data indicate a large diversity of influences controlling CK production and interaction with receptors. Moreover, because CKs are important mediators of immunoinflammatory reactions and they belong to a complex cascade of events in part dependent on inflammatory cytokines.

MEASUREMENTS OF CYTOKINES

The basic goal for the clinical determination of cytokines is the measurement of their physiological and physiopathological concentrations. Thus the definition of physiological concentration is very important in defining the actual biological functions of cytokines. Again, cytokines are different from hormones, which normally act in a distant anatomical region from the site where they are produced (of course, systemic levels will represent a good approach for the physiological concentration of hormones). Cytokines frequently act on the same cell that produced them (autocrine action) or in neighboring cells (paracrine action), leaving the systemic concentration (endocrine action) as a very distant reflection of biological action. Considering present knowledge, only the on-site determination (at the cell membrane or in the intracellular compartment) will be physiologically relevant[2,255,585] except in the case of cytokines, such as IL-1 and IL-6, that have endocrine functions.[2] However, circulating cytokine concentrations may still act as simple disease markers in conditions such as cancer and inflammation. In practice, even in the systemic compartment, it is necessary to study several cytokines (IL-2, IFNγ, IL-4, IL-10, and IL-13) using not only enzyme-linked immunosorbent assay (ELISA) but also PCR techniques.[157]

Requirements

To study local concentrations of cytokines, it is necessary to define the (1) secreted concentration of the cytokine per cell per time unit, (2) number of secretory vesicles fusing with the plasma membrane per time unit, (3) distribution of fusing vesicles on cell surface (normally not evenly spaced), (4) size of secretory vesicles, (5) concentration of cytokines in secretory vesicles, (6) liberation of vesicle contents (normal versus propulsion), and (7) superficial diffusion (over cell membranes) coefficient and time.[255]

In addition, many physiological factors affect the circulating levels of cytokines and their measurement (Figure 22-35). For example, cytokines usually act in a paracrine and autocrine mode by binding to their receptors; only a few cytokines have endocrine actions. In addition, although the circulating levels of cytokines can be high (e.g., IL-6 can reach blood concentrations up to 20,000 pg/mL in severe bacterial infections), their normal circulating levels are typically very low (e.g., a few pg/mL). Thus methods used to

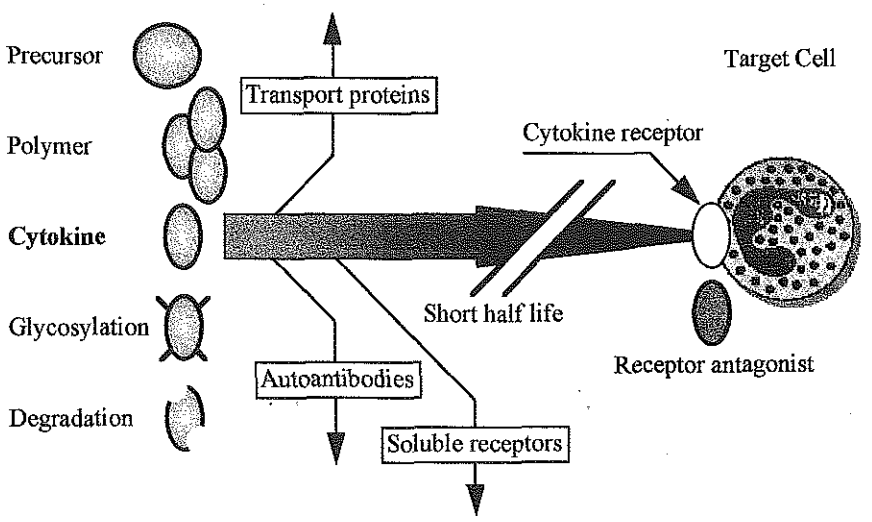

Figure 22-35 Factors influencing the measurement of cytokines.

measure them must have a wide dynamic range and a low limit of detection. The molecular forms of cytokines are very diverse (monomers and polymers), and some are synthesized as precursors (e.g., the 31-kDa precursor of IL-1α is converted by proteolysis to the mature 17-kDa form of IL-1α). Cytokines can also be degraded by proteases, which are produced during the inflammatory process.

Many cytokine inhibitors have been described. Among them, soluble receptors or autoantibodies (with affinity constant sometimes being as high as 10^{-11} mol/L) can influence cytokine assays. Nonspecific inhibitors are represented by plasma proteins, which bind cytokines (e.g., α_2-macroglobulin and IL-6). The presence of such inhibitors can contribute to inaccurate results. The half-lifes of cytokines are also very short (generally a few minutes), which explains the very rapid plasma peaks of these molecules. Furthermore, in some instances, a circadian rhythm has been reported (IL-6 and RA) and intraindividual variation is very high (Figure 22-36).

Sample Collection and Storage

In the measurement of cytokines in body fluids, samples must be collected and stored in the proper manner. The main problems encountered in the collection process include: (1) cytokines can continue to be produced after sample collection by the various cells present in the biological fluid; (2) collection tubes can become contaminated by microorganisms, which are a potent stimulus of cytokine production; (3) cytokines can be degraded in the collection container; and (4) cytokines can bind to cell receptors during storage.

For bioassays, serum collected in pyrogen-free tubes is required. After rapid centrifugation, freezing of the plasma (or serum) at –80 °C is recommended for storage. Freezing-thawing cycles must be prevented.

For immunoassays in biological fluids, ethylenediaminetetraacetic acid (EDTA) plasma is the most suitable sample, because tubes containing heparin are often contaminated by endotoxin, and cytokine release may occur during coagulation. Some investigators recommend the addition of protease inhibitors (Trasylol).

For intracellular cytokine detection by flow cytometry, PBMCs are often used, but to have a more specific analysis, it may be necessary to use cells from other biological fluids (e.g., synovial fluid, cerebrospinal fluid, and bronchoalveolar lavage fluid) or to separate cells according to functional characteristics or expression of membrane antigens (e.g., CD3, CD4, CD8, and CD56).

In practice, all analyses for cytokines must be performed within a narrow interval of time (not more than 5 hours) after sample collection to prevent cellular interactions and possible cytokine release. Blood samples must be collected with endotoxin-free heparin. The same is true for immunoassays dealing with cytokine production by blood cells.

Principles of Cytokine Assays

Bioassay and immunoassay are the analytical techniques of choice to measure cytokines.[463] However, newer instrumental techniques are also beginning to be used to measure cytokines and CKs. These techniques are used to quantify their (1) concentration and activity in biological fluids, (2) production by whole blood cells,[40] (3) concentration of receptors, and (4) intracellular levels.

Bioassays

Historically the functions of cytokines have been elucidated first with bioassays preceding immunoassays for cytokine quantification. The bioassay of a given cytokine is based on its bioactivity in a defined biological model, normally based on a certain cell line. Various approaches have been reported: (1) proliferation tests—induction of cell growth (e.g., B9 cell line for IL-6); (2) tests for cytotoxicity—TNFα on WEHI 164

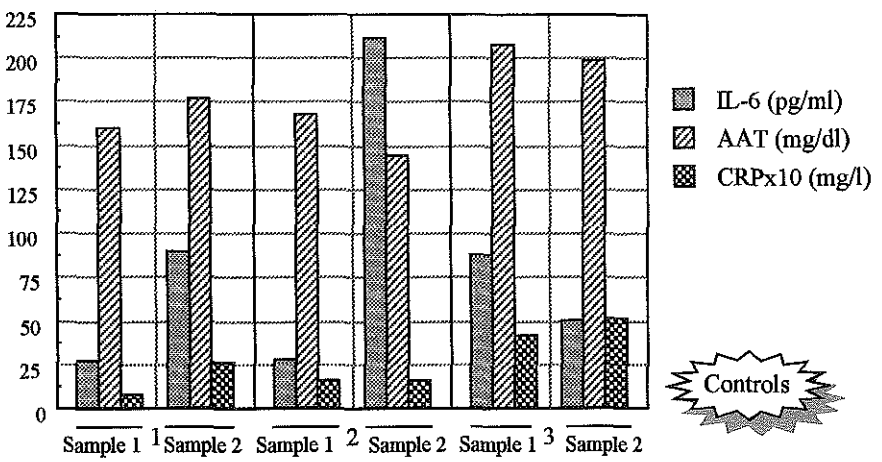

Figure 22-36 Intraindividual variation of IL-6, α_1-antitrypsin (AAT), and C-reactive protein. Data obtained from the analysis of peripheral blood samples obtained from three healthy volunteers. Sample 1 was obtained from each volunteer with sample 2 obtained 2 weeks later.

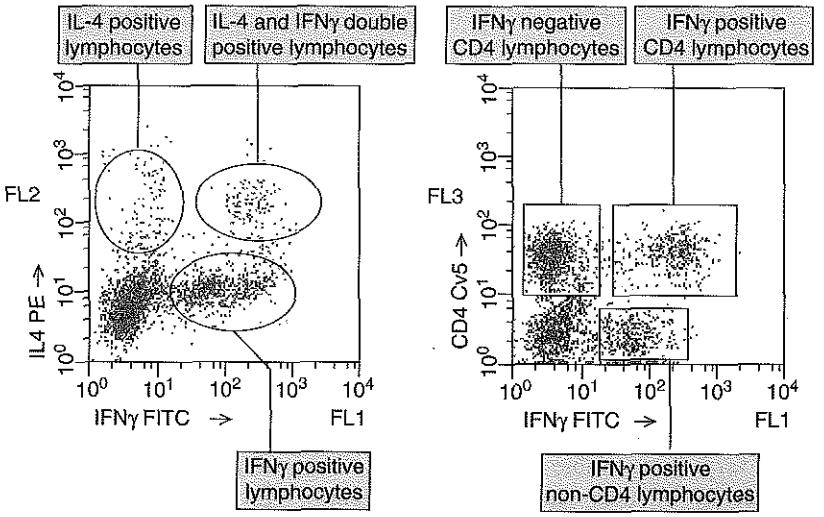

Figure 22-37 Flow cytometric analysis of IL-4 and IFNγ.

cell line, and (3) tests for chemotactic activity—migration of cells in a Boyden chamber or in agarose (e.g., IL-8).

The major drawback of these techniques is their lack of specificity, poor precision (CV = 15% to 100%), and long analysis time (1 to 4 days). Their main advantages are that they measure biologically active molecules and detect as little as 0.1 pg/mL.

A standard method for the quantitation of cytokines is to perform a bioassay in which aliquots of samples are compared with known concentrations of a cytokine in supporting the proliferation of a cytokine-dependent cell line. In most instances, however, these cell lines are dependent on the cytokine not only for proliferation, but also for survival.[58]

Immunoassays

Currently, immunoassay is the practical method of choice for measuring cytokines and their receptors. As cytokines are proteins, specific antibodies can be raised against recombinant cytokines and have also been measured as an indicator of cytokine presence.[146] The general characteristics of cytokine immunoassays are comparable with the classical immunoassays, with monoclonal, oligoclonal, or polyclonal antibodies all being used (see Chapter 9). The most popular formats are immunoradiometric assay (IRMA) and ELISA, which use a first monoclonal antibody for the capture and a second antibody labeled with a radioisotope or an enzyme.

Typically, ELISA assays only measure one cytokine at a time. Depending on the application, this may be a disadvantage, because it may be desirable to measure more than one cytokine. This disadvantage has been overcome with the development and appearance of the "multiplexed" analytical systems that are capable of measuring several cytokines at once.[117,150] An example of such a system is the Luminex 100/xMAP analytical system (Luminex Corp., Austin, Texas); http://www.luminexcorp.com), which is capable of measuring more than 70 cytokines simultaneously. With this system, molecular reactions take place on the surface microspheres. For each reaction in an xMAP profile, thousands of molecules are attached to the surface of internally color-coded microspheres. The assigned color code identifies the reaction throughout the test. Instrumentally the analyzer integrates laser optics, fluidics, a controller, advanced digital signal processing, and a bar code reader into a single compact unit. Other systems incorporate microchip, immunoassay, and flow cytometry to measure cytokines,[81,459,509,559,567] cytokine antibodies,[146,567] or cytokine genes.[113,391]

The main disadvantage of immunoassays is that they measure total cytokine, which contains both functional and nonfunctional levels.[342] Cross-reactivity with the precursors or degradation products of the cytokine is frequently observed. The detection limit (about 1 to 10 pg/mL) of immunoassays is higher than bioassays. A 1995 study reported a lack of comparability between the different kits for IL-2, IL-6, IL-8, and TNFα.[306] The major advantages of immunoassays are their excellent analytical performance and their ability to be automated.

The comparative characteristics of bioassays and immunoassays when applied to cytokine measurements in biological fluids are listed in Table 22-9.[47]

Instrumental Techniques

Instrumental techniques such as capillary electrophoresis, high-performance liquid chromatography,[503] flow cytometry, and multiplexing techniques have been used to measure cytokines or their receptors, antibodies, or genes. For example, flow cytometry has been found useful in measuring intracellular cytokines in less than 2 hours. This gives very useful information about the frequency and cell-surface phenotype of individual cytokine-producing cells. Flow cytometry allows the rapid analysis of sufficiently large numbers of cells previously treated with fixative and permeabilizing agents. Three- to four-color analysis (FL1, FL2, FL3, and FL4) is advised to undertake concomitant cellular identification using antigenic markers (e.g., FL1-IFNγ, FL2-CD3, and FL3-CD4 gives the identification of CD4 T lymphocytes with intracellular IFNγ) as shown in Figure 22-37.

TABLE 22-9 *Comparative Characteristics of Bioassays and Immunoassays**

	Bioassays	Immunoassays
Limit of detection	<1 pg/mL	1-10 pg/mL†
Specificity	Low	High
Precision	CV ≅ 15%-100%	CV ≅ 5%-10%
Assay range	Narrow	Wide
Assay time	1-4 days	A few hours
Calibration	Difficult	Simple
Clinical significance	Biological active molecule	Antigenic presence

*Cytokine measurements in biological fluids.
†New high-sensitivity kits allow detection of 0.1 to 1 pg/mL.

In practice,[463] the main problems experienced by flow cytometric assays are (1) the necessity for a negative control to define the cutoff level (normally the upper limit of the negative control) between positive and negative fluorescent cells; (2) the background induced by autofluorescence (frequently important in bronchoalveolar lavage cells); (3) the nonsuitability of automatic gating of cells; and (4) the complexity of quantifying the number of cytokine molecules inside each cell.

CHAPTER 23

Tumor Markers

Daniel W. Chan, Ph.D., D.A.B.C.C., F.A.C.B.,
Ronald A. Booth, Ph.D.,
and Eleftherios P. Diamandis, M.D., Ph.D.

A tumor marker is a substance produced by a tumor or by the host in response to a tumor that is used to differentiate a tumor from normal tissue or to determine the presence of a tumor based on measurements in the blood or secretions. Such substances are found in cells, tissue, or body fluids and are measured qualitatively or quantitatively by chemical, immunological, or molecular biological methods.[199]

Morphologically, cancer tissue has been recognized by pathologists as resembling fetal tissue more than normal adult differentiated tissue. Tumors are graded according to their degree of differentiation as being (1) well differentiated, (2) poorly differentiated, or (3) anaplastic (without form). Tumor markers are the biochemical or immunological counterparts of the differentiation state of the tumor. In general, some tumor markers represent reexpression of substances produced normally by embryogenically closely related tissue (Table 23-1).

Some tumor markers are specific for one type of cancer, and others are seen in several cancer types. Many of the well-known markers are seen in noncancerous conditions and cancer. Consequently, these tumor markers are not diagnostic for cancer. However, it is thought that the blood levels of tumor markers reflect tumor activity and volume.

Clinically an ideal tumor marker should be both specific for a given type of cancer and sensitive enough to detect small tumors for early diagnosis or during screening. Unfortunately, few markers are specific for a single individual tumor (tumor-specific markers); most are found with different tumors of the same tissue type (tumor-associated markers). They are present in higher quantities in cancer tissue or in blood from cancer patients than in benign tumors or in the blood of normal subjects. In practice, tumor markers are most useful in evaluating the progression of disease status after the initial therapy and monitoring subsequent treatment modalities.[14,15]

This chapter begins with general discussions on (1) cancer, (2) the historical background of tumor markers, (3) their clinical applications, (4) how their utility is evaluated, (5) clinical guidelines for their use, and (6) how they are measured. Several clinically relevant tumor markers from each of these categories are then discussed in detail. These are grouped under the general categories of enzymes, hormones, oncofetal antigens, carbohydrate markers, blood group antigens, proteins, receptors, or genes. More detailed information on tumor markers is found in a 2002 textbook on the subject.[59]

CANCER

In 2004 the estimated number of new cancer cases excluding skin cancer was 1.37 million. Prostate cancer was the leader, followed by cancer of the breast, lung, colon-rectum, and bladder.[31] Together, diseases of the heart and malignant neoplasms account for 52% of all deaths in the United States. Despite heart disease still being the leading cause (699,697 deaths in 2001), malignant neoplasms are a close second (553,251 deaths) and they are projected to surpass heart disease in approximately 10 years.[10] Even in the face of an enormous research effort, the overall mortality rate of cancer has not changed significantly over the past 40 years. However, the trend of cancer mortality varies with individual types of cancer. Significant decreases (greater than 15%) in mortality have been observed in Hodgkin's disease and cancer of the cervix, stomach, and uterus. Alternately, significant increases in mortality (greater than 15%) have occurred in lung cancer, melanoma, multiple myeloma, and non-Hodgkin's lymphoma.[95] These trends support the conclusion that early detection and more effective treatment combined with prevention (e.g., decreasing smoking and improving diet) could greatly reduce the mortality rate of cancer in the future.

TABLE 23-1 "Levels" of Expression of Oncodevelopmental Markers

Production of Tumor Markers by Various Tissues				
Marker	**Normal Producing**	**Embryogenically Closely Related**	**Distantly Related**	**Unrelated**
CEA	Colon	Stomach, liver, pancreas	Lung, breast	Lymphoma
AFP	Liver, yolk sac	Colon, stomach, pancreas	Lung	
hCG	Placenta	Germinal tumors	Liver	Epidermal lung
Serotonin	Enteroendocrine carcinoid	Adrenal	Oat cell, lung	Epidermal lung

Modified from Sell S. Cancer markers. In: Moossa AR Schempff SC, Robson MC, eds. Comprehensive textbook of oncology, 2nd ed, Vol. 1. Baltimore: Williams & Wilkins, 1991: 225-38.
CEA, Carcinoembryonic antigen; *AFP,* alpha fetoprotein; *hCG,* human chorionic gonadotropin.

A simple definition of cancer is "a relatively autonomous growth of tissue."[175] Understanding the cause of autonomous growth would clearly facilitate the search for a cure. A *carcinogen* is an agent that causes cancer. A carcinogen may be physical (e.g., radiation), chemical (e.g., a polycyclic hydrocarbon), or biological (e.g., a virus). Exposure to such an agent may cause cancer either by producing direct genotoxic effects on deoxyribonucleic acid (DNA) (e.g., as with radiation) or by increasing cell proliferation (e.g., by a hormone), or both (e.g., through the use of tobacco).

Advances in molecular genetics have provided a better understanding of the genesis of human cancer. The proliferation of normal cells is thought to be regulated by growth-promoting *oncogenes* and counterbalanced by growth-constraining *tumor suppressor genes.* The development of cancer appears to involve the activation or the altered expression of oncogenes[1] or the loss or inactivation of a tumor suppressor gene.[246] A pathway to cancer development has been published.[66]

Early detection of cancer offers the best chance for cure. The goal is to diagnose cancer when a tumor is still small enough to be completely removed surgically. Unfortunately, most cancers do not produce symptoms until the tumors are either too large to be removed surgically or until cancerous cells have already spread to other tissue (metastasized).

Although other modes of therapy, such as administration of chemical toxins or irradiation, are often effective in destroying most tumor cells, they are usually not curative. The few residual viable tumor cells are able to proliferate, develop resistance to further therapy, and eventually kill the patient.

HISTORICAL BACKGROUND

The first tumor marker reported was the Bence Jones protein. Since its discovery in 1847 by precipitation of a protein in acidified boiled urine,[17] the measurement of Bence Jones protein has been a diagnostic test for multiple myeloma (a tumor of plasma cells). More than 100 years after its discovery, the Nobel Prize–winning studies of Porter and of Edelman and Poulik identified the Bence Jones protein as the monoclonal light chain of immunoglobulin secreted by tumor plasma cells. Monoclonal paraproteins appear as sharp bands in the globulin area in electrophoretic patterns of serum. Diagnosis of multiple myeloma is often made based on this finding or on the presence of an elevated level of "monoclonal" immunoglobulin in the serum.[213]

A brief history of tumor markers is shown in Table 23-2.[197] The first period of tumor marker history was the era of the Bence Jones protein. The second era, from 1928 to 1963, included the discovery of hormones, enzymes, isoenzymes, and proteins and their application to the diagnosis of cancer and the beginnings of the chromosomal analysis of tumors. Occasionally, such markers were useful in the diagnosis of individual tumors, but the general application of tumor markers for monitoring cancer patients did not start until the third era with the discovery of alpha fetoprotein (AFP) in 1963[2] and carcinoembryonic antigen (CEA) in 1965.[80] The production of such markers during fetal development and in tumors led to the use of the term *oncodevelopmental markers.*[71]

The fourth era started in 1975 with the development of monoclonal antibodies and their subsequent use to detect oncofetal antigens and antigens derived from tumor cell lines. Examples are carbohydrate antigens such as CA 125, CA 15-3, and CA 27.29. Advances in molecular genetics using molecular probes and monoclonal antibodies to detect chromosome or protein alterations, including the study of oncogenes, suppressor genes, and genes involved in DNA repair,[115] have led to the rapid understanding and use of tumor markers at the molecular level. These markers are becoming increasingly useful at the cellular level. For example, mutated *ras* oncogene can be detected in sloughed cellular DNA in fecal material and thus can be used to diagnose colon cancer.[204] Discovery of the breast cancer susceptibility genes, *BRCA 1* and *BRCA 2,*[144,251] has led to the possibility of screening for familial breast cancer in high-risk individuals.[174]

As we begin the twenty-first century, new technologies are being applied to the discovery of tumor markers and their

clinical applications. Notable among these discoveries are the introduction of genomics and proteomics technologies[162] such as the measurement of complementary DNA (cDNA) protein and the tissue microarrays and the use of mass spectrometry as a diagnostic and discovery tool. Furthermore, the advent of bioinformatic techniques, including neural networks, logistic regression, and other algorithms, is facilitating the use of multiparametric analysis for cancer diagnosis, prognosis, and prediction of therapy.[263]

CLINICAL APPLICATIONS

The potential uses of tumor markers are summarized in Table 23-3. In general, tumor markers may be used for diagnosis, prognosis, and monitoring the effects of therapy and as targets for localization and therapy.[199] Ideally a tumor marker should be produced by the tumor cells and be detectable in body fluids. It should not be present in healthy people or in benign conditions. Therefore it could be used for screening for the presence of cancer in asymptomatic individuals in a general population. Most tumor markers are present in normal, benign, and cancer tissues and are not specific enough to be used for screening cancer. However, if the incidence of cancer is high among certain populations, screening could be feasible. An example is the use of AFP in the screening of hepatocellular carcinoma in China and Alaska.[141] Prostate-specific antigen (PSA) has been used in conjunction with digital rectal examination for early detection of prostate cancer. Because of the elevation of serum PSA in benign prostatic hyperplasia (BPH), PSA velocity and free PSA have been used to improve the detection of prostate cancer.[167]

The clinical staging of cancer is aided by quantitation of the marker (i.e., the serum level of the marker reflects tumor burden). The marker value at the time of diagnosis may be used as a prognostic indicator for disease progression and patient survival. This is possible for an individual patient, but different levels of markers produced by different tumors do not usually allow one to determine the prognosis of a tumor from the initial level. However, after successful initial treatment, such as surgery, the marker value should decrease. The rate of the decrease can be predicted by using the half-life of the marker. For example, the half-life of PSA is 2 to 3 days, that of human chorionic gonadotropin (hCG) is 12 to 20 hours, and that of AFP is 5 days. If the half-life after treatment is longer than the expected half-life, then the treatment has not been successful in removing the tumor. The magnitude of marker reduction may, however, reflect the degree of success of the treatment or the extent of disease involvement.

Detecting cancer recurrence may be helpful to initiate early treatment or change therapy. Ultrasensitive PSA assays allow earlier detection of prostate cancer after radical prostatectomy. The breast cancer marker CA 27.29 has been shown to detect recurrent disease before any clinical evidence in breast cancer patients receiving adjuvant chemotherapy.[39]

Most tumor marker values correlate with the effectiveness of treatment and responses to therapy. In breast cancer, the concentration of markers, such as CA 15-3 or CA 27.29, changes with the treatment and the clinical outcome of the patient. Marker values usually increase with progressive disease, decrease with remission, and do not change significantly with stable disease. The tumor marker kinetics in the monitoring of cancer may be more complicated. The marker values in response to treatment may show an initial delay before demonstrating the expected pattern of change.[110]

In addition, antibodies to tumor markers labeled with a radioactive tag are used to localize the tumor masses (radioimmunoscintigraphy)[52] or to provide direction for labeled antibodies to attack the tumor site. Examples are the use of radiolabeled antibodies to CEA to localize colon tumors and the application of labeled antibodies against ferritin to target hepatocellular carcinoma. This approach is

TABLE 23-3 Current Applications of Tumor Markers and Their Limitations

Application	Current Usefulness	Comments
Screening for cancer	Limited	1. For screening, you must have a marker that is elevated at early disease stages, when the disease is localized and potentially curable. Most circulating cancer markers (with the exception of PSA) are elevated notably in the late stages of disease. Thus diagnostic sensitivity is usually low for early-stage disease. 2. With the exception of PSA, most cancer markers are not specific for a particular tissue and elevations may be due to diseases of other tissue, including benign and inflammatory diseases. Thus diagnostic specificity may be low, leading to many false positives. In screening, there is a necessity for a definitive diagnostic method that will separate true positives from false positives. If this procedure is invasive (e.g., surgery) and/or expensive, patients will not accept it. 3. Screening, even if effective for early cancer diagnosis, must demonstrate benefit to the screened population in terms of survival or other clinical endpoints.
Diagnosing cancer	Limited	Same as above. Low diagnostic sensitivity and specificity. However, for selected subgroups of high-risk patients, in whom the chance of cancer is high (high prevalence), tumor marker analysis may not aid the clinician in ordering more elaborate testing (e.g., imaging techniques or laparoscopic investigations).
Evaluating cancer prognosis	Limited	Most cancer markers have prognostic value but their accuracy is not good enough to warrant specific therapeutic interventions. For example, higher preoperative levels of PSA are associated with capsular penetration, high Gleason score, positive surgical margins, and positive lymph node status, but the decision to treat with two different modalities (e.g., radical prostatectomy versus nonsurgical approaches) cannot be made based on tumor marker data alone. Same applies to many other cancers.
Prediction of therapeutic response	Important	Despite the importance of using biomarkers in predicting response to specific therapies, very few known markers have such predictive power. These include the steroid hormone receptors for predicting response to antiestrogens and Her-2/neu amplification for predicting response to Herceptin in breast cancer patients. We must have more predictive markers to individualize therapy and maximize clinical response.
Tumor staging	Limited	Same as for prognosis. The data are not good enough for accurate staging unless the value is reflecting tumor volume.
Detecting tumor recurrence or remission	Controversial	Despite the importance of using biomarkers to detect cancer relapse, current markers are limited by the following: (a) Lead time is short (weeks to a few months) and does not significantly affect outcome, even if therapy is instituted earlier; (b) Therapies for treating recurrent disease are not effective at present; (c) In certain groups of patients, biomarkers are not produced and do not detect relapses; (d) Sometimes biomarkers provide misleading information (e.g., clinical relapses occur without biomarker elevation, or biomarker is elevated nonspecifically, without progressive disease, leading to either overtreatment or discontinuation of a current and successful treatment protocol).
Localizing tumor and directing radiotherapeutic agents	Limited	Only a few biomarkers are available for this application and success is limited at present

TABLE 23-3 Current Applications of Tumor Markers and Their Limitations—*Continued*

Application	Current Usefulness	Comments
Monitoring the effectiveness of cancer therapy	Important	For patients with advanced disease, who are treated with various modalities, it is important to know if therapy works. In this regard, biomarkers usually provide information that is readily interpretable and more economical, more sensitive, and safer than radiological or invasive procedures. For certain cancers, this may facilitate increased enrollment of patients into therapeutic clinical trials.

Modified from Diamandis EP. Tumor markers: Past, present, and future. In: Diamandis EP, Fritsche HA, Lilja H, Chan DW, Schwartz MK. Tumor markers: Physiology, pathobiology, technology, and clinical application. Washington DC: AACC Press, 2002:5.

also used for treatment by allowing the antibody to bind to the tumor marker epitopes and kill the tumor cell with the dose of radioactivity.[245]

EVALUATING CLINICAL UTILITY

To evaluate the clinical usefulness of a tumor marker, it is necessary to establish reference values, calculate predictive values, evaluate the distribution of marker values, and determine the role of the values in disease management.

Reference Values

Reference values of a tumor marker are obtained from a healthy population, preferably with age- and sex-matched individuals.[26] The determination of reference values is time-consuming and requires a large healthy population ($n \geq 120$ subjects). Statistical analysis using the mean ± 2 standard deviation (SD) for a population with a gaussian (normal) distribution is a frequently used method. For a nongaussian distribution, the percentile method is a simple approach and often used (for further discussion of reference values, see Chapter 16).

The reference values determined using healthy subjects in this fashion are applicable to analytes with physiologically well-defined concentrations. For testing with relatively specific applications, such as the use of tumor markers in the diagnosis and management of cancer, a decision level may be more appropriate than the upper limit of the normal population. In most cases, using benign patients as the nondisease group is more appropriate than using a healthy population. The decision level can be determined using a predictive value model.

Predictive Value Model

The predictive value model includes the clinical sensitivity, specificity, and predictive value of a test. By varying the decision level, clinical sensitivity and specificity will change in opposite directions. An optimal decision level can be selected based on the strategies outlined in Chapter 15.

A useful approach to evaluating multiple tests for the same analyte or multiple markers for the same type of cancer

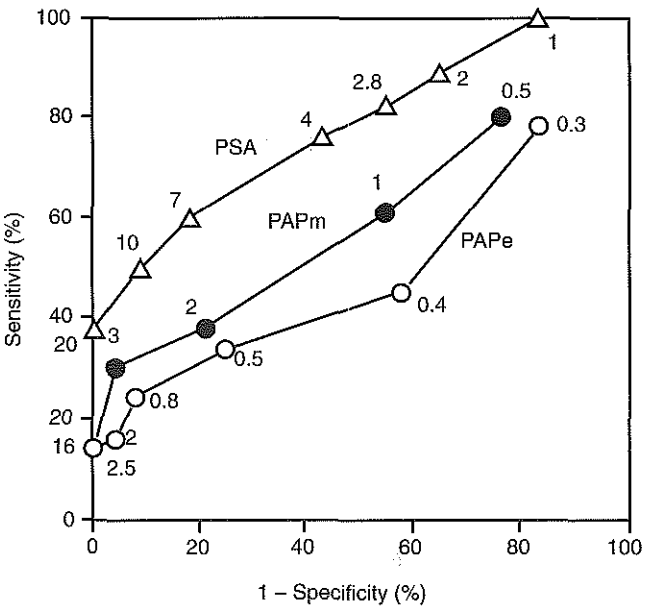

Figure 23-1 ROC curves for PSA, prostatic acid phosphatase by monoclonal immunoassay (M-PAP), and enzymatic prostatic acid phosphatase (E-PAP). The data for all 128 patients with prostatic disease are plotted, with several quantitative decision levels (as indicated in the figure) for each assay. Units are μg/L for M-PAP and PSA, and U/L for E-PAP. *(From Rock RC, Chan DW, Bruzek DJ, et al. Evaluation of a monoclonal immunoradiometric assay for prostate-specific antigen. Clin Chem 1987; 33:2257-61.)*

is the *receiver operating characteristic* (ROC) curve (see Silver and co-workers).[207] The ROC curve can be constructed by plotting sensitivity versus 1 minus specificity or the true-positive rate versus the false-positive rate. The advantage of the ROC curve is the display of performance over the entire range of decision levels. One can pinpoint the decision level where the optimal sensitivity and specificity can be achieved. By superimposing the ROC curves of several markers, the most predictive marker can be selected. Examples are shown in Figures 23-1 and 23-2. The preparation of an ROC curve has been discussed in detail by Zweig and Robertson[266] and in Chapter 15.

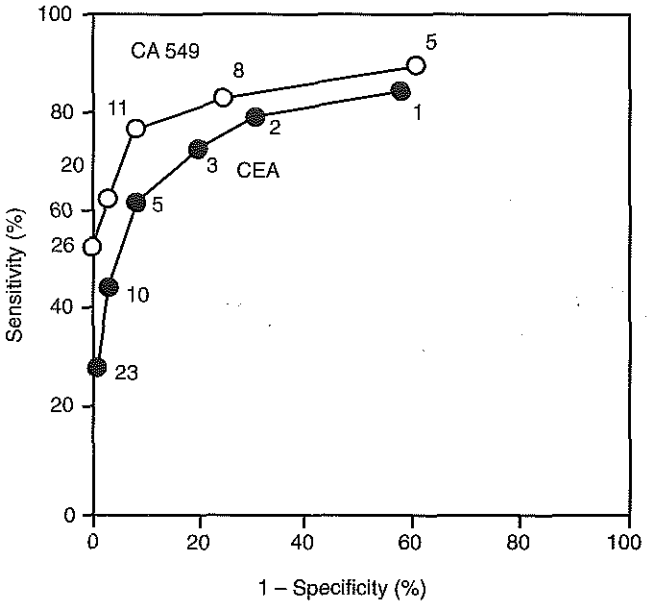

Figure 23-2 ROC for CA 549 (kU/L) and CEA (μg/L). The sensitivity, specificity, and efficiency are based on the decision level of CA 549 (11 kU/L) and CEA (5 μg/L). The data include patients with breast cancer and benign breast diseases (331 for CA 549, and 322 for CEA). The decision values are indicated on the curve. *(From Chan DW, Beveridge RA, Bruzek DJ, et al. Monitoring breast cancer with CA 549. Clin Chem 1988; 34:2000-4.)*

Distribution of Marker Values

Application of the predictive value model is difficult for analytes that are not diagnostic for a single disease. Levels of most, if not all, tumor markers are elevated in more than one disease condition. When using the predictive value model, it is necessary to select a population that includes groups with and without disease. What patients should be included in these two groups? The decision should be based on the specific clinical questions asked. If the question concerns the diagnostic sensitivity of CEA for active colorectal carcinoma, the disease group should include only those patients with active colorectal carcinoma. Selection of the nondisease group is more challenging. Should healthy individuals and those with benign conditions be included? If so, how many benign condition groups should be included? Should the patients in remission be included as well, because they do not have active diseases? The values calculated for sensitivity and specificity greatly depend on the types of groups included and on the number of patients in each group (see Chapter 15 for a discussion on the effect of spectrum on sensitivity and specificity).

The distribution of tumor marker values is usually shown as the percentage of patients with elevated values as determined using various cut-off values in the healthy, benign, and cancerous groups. International staging criteria should be used to classify cancer patients. Diagnosis should be based on pathological findings. The groups are selected from past experiences of similar markers. In breast cancer, for example (Table 23-4), normal women are used as the healthy population for comparison. The nonmalignant or benign groups are selected to include people with the most likely causes of marker elevation: benign liver and breast diseases and pregnancy. The nonbreast metastatic cancer groups are selected to show the specificity of the marker using endometrial, colon, lung, prostate, and ovarian carcinoma.

Grouping all breast cancer patients into a single category is not satisfactory because most markers are elevated in active breast cancer. The adjuvant group consists of patients who had no metastasis, underwent mastectomy and treatment with adjuvant chemotherapy, and have no evidence of disease. The marker value is not expected to be elevated. The metastasis group includes patients in complete remission, in partial remission, or with progressive breast cancer accompanied by local or distant metastases. The progressive breast cancer group should have the highest percentage of elevated marker values. The partial remission group should have an intermediate percentage of elevated marker values. The complete remission group should have the lowest percentage of elevated marker values.

Disease Management

Most tumor markers are used to monitor treatment and progression of cancer. The selection of patient groups is important to illustrate the usefulness of the marker in various clinical settings. Markers may be used to determine the success of the initial treatment (e.g., surgery or radiation), detect the recurrence of cancer, and monitor the effectiveness of the treatment modality.

To determine the success of surgery, an elevated marker level before surgery should fall after a successful operation. The extent of the decrease in the marker value depends on the pretreatment tumor involvement.

With the recurrence of cancer after a successful initial treatment, the marker value may not fall within the normal half-life. It may fall to a steady level that is higher than normal, or it may fall within the reference interval of healthy individuals. A subsequent rise in the marker value suggests recurrence of the cancer. An example of breast cancer is shown in Figure 23-3.

To monitor the effectiveness of cancer therapy, the marker value should increase with the progression of cancer, decrease with the regression of cancer, and not change in the presence of stable disease. When evaluating candidate markers, all the events related to the progression, stability, and regression of disease can be grouped; whether the marker value changes in the predicted direction in all these situations can be evaluated next.[38]

The Working Group on Tumor Marker Criteria of the International Society for Oncodevelopmental Biology and Medicine has published the following criteria for the interpretation of changes in tumor marker values[26]:

"If no therapy is given, at least a linear increase in three

TABLE 23-4 Distribution of CA 549 Values

consecutive samples (i.e., two time intervals) on a log scale should be registered to establish a recurrence. Usual intervals could be three months but are clinically determined. After a first increase, next samples should be taken after 2 to 4 weeks, irrespective of the absolute level."

If therapy is given, the changes in marker values should reflect the clinical progression of the disease. "Progressive disease is defined by an increase in the marker level of at least 25%. Sampling should be repeated within 2 to 4 weeks for additional evidence. . . . The sampling interval during therapy may depend on the type of tumor and should be related to clinical follow-up." A decrease in marker value of at least 50% is indicative of partial remission "with the concept that tumor load is related to the changes in serum tumor marker levels." The working group also provided a general opinion that "a complete remission cannot be determined by marker levels, but if tumor marker levels are elevated, the clinical decision of complete remission based on conventional methods should be considered incorrect unless an explanation for the presence of the elevated level is given."

CLINICAL GUIDELINES

The diagnosis and staging of cancer involve a number of tools, including physical examination, imaging, and laboratory studies. Application of these tools has resulted in a number of tumor markers that are used for screening, diagnosis, staging, and prognosis, and for directing treatment modalities. However, not all tumor markers are appropriate for all uses, and not all cancers have established tumor markers. Therefore each type of cancer and each tumor marker must be properly evaluated for use, and clinicians must be educated to the proper use of the tumor markers to conserve resources.

A number of international groups have released guidelines on the selection and use of tumor markers in the clinic. These groups include the National Academy of Clinical Biochemistry (NACB), the European Group on Tumor Markers (EGTM), the American Cancer Society (ACS), the American Society for Clinical Oncology (ASCO), and others.[230] All of these groups are composed of experts in the areas being assessed, and a number of criteria are used to form the recommendations, including the level of evidence for the tumor marker (level I to V, with level I being a high-powered prospective trial) and the tumor marker utility grading system (TMUGS).[59] Table 23-5 summarizes the recommendations of a number of these groups.

ANALYTICAL METHODOLOGY

Tumor markers are measured by a variety of analytical techniques including enzyme assay (Chapters 8 and 21); immunoassay (Chapter 9); receptor assay and instrumental techniques such as chromatography (Chapter 6); electrophoresis (Chapter 5); mass spectrometry interfaced with either liquid or gas chromatographs (Chapter 7) and microarrays. Details of these techniques are found in the indicated chapters. Here we expand on the use of mass spectrometry and microarrays for the assay of protein and genetic tumor markers.

MASS SPECTROMETRY

Mass spectrometry for small molecules has been used in the clinical laboratory for more than 40 years. However, recent

TABLE 23-5 Summary of Key Guideline Recommendations

Cancer Type	NACB	ASCO	ACS	EGTM
Breast	ER and PR on all cancers. CA 15-3/CA 27.29 for monitoring advanced disease	Routine use of CA 15-3 or CA 27.29 alone *not* recommended Increasing CA 15-3 or CA 27.29 may be used to suggest treatment failure. Routine use of CEA not recommended. ER and PR determined for primary lesions. Steroid hormone receptors to be used to select patients for endocrine therapy. HER-2/neu (c-ErbB-2) overexpression or amplification may be used to select patients for Herceptin (trastuzumab) therapy	None	Steroid receptors in tissue predicting response to hormone therapy CEA and one MUC1-gene-related protein in serum for prognosis, follow-up, and monitoring of therapy HER-2/neu in tissue for predicting response to Herceptin (trastuzumab) in patients with advanced disease
Ovarian	CA 125 as a diagnostic aid and for monitoring therapy	None	None	CA 125 as an aid in diagnosis, for monitoring treatment, and early prediction of recurrence
Prostate	PSA with DRE. %fPSA when PSA is between 4-10 ng/mL and DRE is negative	Guidelines under development for metastatic disease	PSA and DRE for screening and detection	tPSA with DRE for screening (studies), case finding, or prognosis.

"None" indicates that the relevant group has not yet considered this type of cancer.

Placental alkaline phosphatase (PLAP) is for monitoring of seminomas in nonsmokers only.

developments have allowed for the mass spectrometric identification of high molecular weight compounds, including proteins and nucleic acids. The new ionization technologies were recognized by the Nobel Prize in chemistry in 2002. These advances triggered investigations toward using the technology for either cancer diagnosis or prognosis or for discovering new cancer biomarkers. In one approach, serum or other fluids from cancer patients or controls are treated with various absorbing surfaces, such as ion-exchange, hydrophobic, or metal-binding chips. After washing out excess proteins, the chips are subjected to mass spectrometric analysis by using the so-called MALDI method (matrix-assisted laser desorption ionization) or SELDI (surface-enhanced laser desorption ionization)-TOF (time-of-flight mass spectrometry). This analysis generates a number of peaks of various M-Z (mass to charge) ratios. By comparing these proteomic patterns with patterns obtained from samples from normal individuals, and by using sophisticated bioinformatic and computational tools, it is possible to identify patterns that are only associated with cancer. This technology has now been investigated for diagnosis of ovarian[171,178,264] prostate,[3,172] bladder, and many other cancers.[186] The technology has been reviewed.[162,173,219] The diagnostic sensitivities and specificities of this technology are impressive and surpass those achieved by using current cancer biomarkers.[3,171,172] However, this method has not as yet been prospectively evaluated but clinical trials are now in progress. Also, a number of shortcomings of this technology have been identified.[56-58]

The same technology and principles are also being used to identify novel cancer biomarkers.[125,178,186,264] To date, a number of molecules have been identified, including apolipoprotein A1, transthyretin fragment, interalpha-trypsin inhibitor, haptoglobin-alpha subunit, and vitamin D–binding protein. These molecules are present in serum at concentrations much higher than levels of traditional cancer biomarkers. The clinical evaluation of these proteins as candidate biomarkers is still under investigation.

Microarrays

A microarray is a microchip of silicon that contains a large number of elements ("spots") in a two-dimensional array (see Chapter 10). To each of these spots is attached different molecules of immobilized short oligonucleotides (e.g., the Affymetrix chips), cDNAs of various genes, proteins, antibodies, etc.[129,152,193] It is possible to immobilize up to 20,000 to 40,000 elements on such chips and, consequently, genome-wide analysis at both the messenger ribonucleic acid (mRNA) and protein levels is now possible. Applications of microarrays include quantitative assessment of gene expression, detection of mutations and polymorphisms (such as single nucleotide polymorphisms), DNA sequencing, and study of protein expression and protein-protein interactions. For some applications, the method has been semiautomated.

These devices have been used to discover new candidate biomarkers. For example, Welsh and colleagues used microarray analysis of gene expression profiles of normal and cancerous tissues and identified highly overexpressed genes in ovarian and other cancers.[247,248] These overexpressed genes were then to be evaluated further with more quantitative techniques, such as reverse-transcriptase polymerase-chain reaction, to confirm the overexpression. The identification of an overexpressed gene can be followed by development of assays to measure the protein and then evaluate it as a serological or tissue biomarker.[247] Some successes of this process have recently been reported (e.g., the identification of osteopontin and HE4 as ovarian cancer biomarkers).

Another application of microarrays is in the classification of cancers based on their gene expression profiles. There are now numerous examples of subclassifying breast, ovarian, prostate, brain, hematological, and other cancers using this technology.[109,170] Especially for breast cancer, it has recently been realized that tissue microarray analysis may stratify patients according to prognosis.[239,240] These analyses aid in the selection of adjuvant therapy. Van de Vijver et al have shown that a relatively small number of genes (about 70) can be used to classify patients in high- and low-risk groups. As of June 2003, this method has been applied clinically to select breast cancer patients for adjuvant chemotherapy.

The application of microarrays for cancer classification and prognosis and for discovering new cancer biomarkers is relatively new. This method has the potential to revolutionize cancer prognosis and prediction of therapy by using dedicated chips. Further standardization is necessary.

ENZYMES

Enzymes were one of the first groups of tumor markers identified. Their elevated activities were used to indicate the presence of cancer.[83] Measurement of enzymes was relatively easy using spectrophotometric determination of enzymatic activities. With the introduction of radioimmunoassay (RIA) in the late 1950s, the mass of an enzyme could be measured as a protein antigen instead of its catalytic activity.

With few exceptions, an increase in the activity or mass of an enzyme or isoenzyme is not specific or sensitive enough to be used for identifying the type of cancer or the specific organ involvement. An exception is PSA. PSA has mild protease activity and amino acid sequence homology with serine protease of the kallikrein family.[46,54] It is expressed by normal, benign, hyperplastic, and cancerous prostate glands and minimally by other tissue.[23] Until the application of PSA as a marker for prostate cancer, tumor enzymes had lost most[83,196] of their popularity for use as cancer markers. Enzymes were used historically as tumor markers before the discovery of oncofetal antigens and the advent of monoclonal antibodies.[195] The abnormalities of enzymes as a marker for cancer are either the expression of the fetal form of the enzyme (isozyme) or the ectopic production of enzymes.

Enzymes are present in much higher concentrations inside the cell. Enzymes are released into the systemic

TABLE 23-6 Enzymes as Tumor Markers

Enzyme	Assay	Type of Cancer
Alcohol dehydrogenase	Act	Liver
Aldolase	Act	Liver
Alkaline phosphatase	Act	Bone, liver, leukemia, sarcoma
Alkaline phosphatase-placental	Act	Ovarian, lung, trophoblastic, gastrointestinal, seminoma, Hodgkin's
Amylase	Act	Pancreatic, various

circulation as the result of tumor necrosis or of the change of the membrane permeability of the cancer cells. Increased enzyme levels are also observed in the blockage of pancreatic or biliary ducts and in renal insufficiency. The intracellular location of the enzyme may also determine the rate of the release. By the time enzymes are released into the systemic circulation, the metastasis of tumors may have occurred. Most enzymes are not unique for a specific organ. Therefore enzymes are most suitable as nonspecific tumor markers. Elevated enzyme levels may signal the presence of malignancy.

Isoenzymes and multiple forms of enzymes may provide additional organ specificity. Table 23-6 summarizes various enzymes, their associated types of malignancy, and the assays used to measure their activity (Act) or their mass concentration (RIA or immunometric assay). Enzymes are traditionally measured by their activities. With the introduction of antibody techniques, some enzymes, such as PSA, are measured as protein antigens rather than by their enzyme activity.

Alkaline Phosphatase

Alkaline phosphatase may arise from liver, bone, or placenta. The alkaline phosphatase in the sera of normal adults comes primarily from the liver or biliary tract. Elevated levels of alkaline phosphatase are seen in primary or secondary liver cancer. Its level may be helpful in evaluating metastatic cancer with bone or liver involvement. Greatest elevations are seen in patients with osteoblastic lesions, such as in prostatic cancer with bone metastases. Minimum elevations are seen in patients with osteolytic lesions, such as breast cancer with bone metastases.[70,229]

In liver metastases, the serum alkaline phosphatase level shows a better correlation with the extent of liver involvement than those of other liver tests. To differentiate the origin of elevated alkaline phosphatase levels, tests of other liver enzymes may be performed, such as that for 5′-nucleotidase or γ-glutamyltransferase. Determination of alkaline phosphatase isoenzymes may provide additional specificity. The liver isoenzyme is thermally more stable than the bone isoenzyme (see Chapter 21 for a more detailed discussion). Other malignancies, such as leukemia, sarcoma, and lymphoma complicated with hepatic infiltration, may also show elevated alkaline phosphatase levels.

Placental alkaline phosphatase (PALP) is synthesized by the trophoblast and is elevated in sera of pregnant women. PALP was first identified as the Regan isoenzyme in 1968 by Fishman and colleagues[71] and was recognized as one of the first oncodevelopmental markers along with AFP and CEA. It is elevated in a variety of malignancies, including ovarian, lung, trophoblastic, and gastrointestinal cancers; seminoma; and Hodgkin's disease.

Creatine Kinase

Creatine kinase (CK) catalyzes the phosphorylation of creatine by adenosine triphosphate. CK is a dimer consisting of two subunits, M (muscle) and B (brain). There are three isoenzymes, CK1 (BB), CK2 (MB), and CK3 (MM). CK1 is present in the brain, prostate gland, gastrointestinal tract, lung, bladder, uterus, and placenta. Cardiac muscle has the highest concentration of CK2 (≅ 20%). CK3 is present in skeletal and cardiac muscles.

Elevated levels of CK1 have been demonstrated in prostate cancer and small cell carcinoma of the lung. Although it is also elevated in other malignancies, such as those of the breast, colon, ovary, and stomach, the clinical usefulness of CK1 as a tumor marker requires further investigation.[196] CK isoenzymes have been included in a prostate cancer panel, "ProstAsure."[12,221]

Lactate Dehydrogenase

Lactate dehydrogenase (LD) is an enzyme in the glycolytic pathway and is released as the result of cell damage. The elevation of LD in malignancy is rather nonspecific. It has been demonstrated in a variety of cancers—including liver, non-Hodgkin's lymphoma, acute leukemia, nonseminomatous germ cell testicular cancer, seminoma, neuroblastoma, and other carcinomas, such as breast, colon, stomach, and lung cancer. The serum LD level has been shown to correlate with tumor mass in solid tumors and provides a prognostic indicator for disease progression. Its value in the monitoring of therapy is rather limited. The isoenzymes only provide marginal specificity for organ involvement. For example, the elevation of the LD5 isoenzyme is associated with liver metastases. The elevation of LD5 in the spinal fluid may be an early indication of central nervous system metastases.[196]

Neuron-Specific Enolase

Enolase is a glycolytic enzyme also known as phosphopyruvate hydratase. *Neuron-specific enolase* (NSE) is the form of enolase found in neuronal tissue and in the cells of the diffuse neuroendocrine system and the amine precursor uptake, and decarboxylation (APUD) tissue. NSE is found in tumors associated with the neuroendocrine origin, including small cell lung cancer (SCLC), neuroblastoma, pheochromocytoma, carcinoid, medullary carcinoma of the thyroid, melanoma, and pancreatic endocrine tumors.

Serum NSE level may be measured by RIA. The upper reference limit is 12.5 μg/mL. In patients with SCLC, the sensitivity is reported to be 80%. The specificity is at least 80% to 90%. The NSE level appears to correlate with stages and provides a useful prognosis for disease progression. The value of NSE in detecting disease relapse has not been proven. Although the findings are mixed, NSE also appears to be useful in monitoring chemotherapy and correlates with disease state. The immunostaining of NSE may also provide differential diagnosis between SCLC and other histological carcinoma types.

Among children with advanced neuroblastoma, more than 90% have been reported to have elevated serum levels of NSE. High levels of NSE are associated with poor prognosis. The levels seem to correlate with the stage of the disease. Monitoring therapy using serum NSE is controversial, particularly with respect to the issue of specificity. However, elevated levels of NSE in children with stage IV neuroblastoma were associated with a poorer outcome.[260]

Prostatic Acid Phosphatase

The acid phosphatases include all phosphatases that hydrolyze phosphate esters with an optimum pH of less than 7.0. They are present in the lysozymes of the secretory epithelial cells. Although acid phosphatase is produced primarily by the prostate gland, it is also found in erythrocytes, platelets, leukocytes, bone marrow, bone, liver, spleen, kidney, and intestine.

Prostatic acid phosphatase (PAP), with an optimum pH of 5 to 6, is very labile at a pH of greater than 7.0 and a temperature greater than 37 °C. It can be distinguished from other acid phosphatases by using tartrate, which strongly inhibits the prostatic form. Another approach is to select substrates that are more specific for PAP. Two substrates commonly used are thymolphthalein monophosphate and β-naphthol phosphate. These two substrates are hydrolyzed by PAP much more quickly than by the other acid phosphatases. Thymolphthalein monophosphate appears to be more specific. Acid phosphatase was first used as a tumor marker in 1938 by Gutman and colleagues.[83] PAP was measured first by its enzymatic activity, then using counterimmunoelectrophoresis, and subsequently, in the late 1970s, by RIA. Its use was proposed as a screening tool for prostate cancer. It has been used to help stage prostate cancer, to correlate with the prognosis of the disease, and to monitor therapy. Elevated serum PAP may be seen in malignant conditions, such as osteogenic sarcoma, multiple myeloma, and bone metastases of other cancers. It may also be elevated in some benign conditions, such as BPH, osteoporosis, and hyperparathyroidism.

The clinical use of PAP has been replaced by PSA. PAP is not as sensitive as PSA for screening or for detection of early cancer. The clinical use of PAP is restricted to confirmation of metastatic prostate cancer and staging of prostate cancer.[6,30] It is less likely to be elevated in BPH than is PSA. Currently the method of choice for PAP is the measurement of its enzymatic activity.

Kallikreins

Kallikreins are a subgroup of the serine protease enzyme family, three of which have been assigned a specific biological role.

Biochemistry

The human kallikrein (hK) gene locus spans a region of approximately 300 kb of chromosome 19q13.4, which

contains 15 tandemly localized kallikrein genes (*KLK1* to *KLK15*) with no intervention from other genes. This is the largest cluster of serine proteases within the human genome. The members of the kallikrein family are identified by a number of similar features.[61] They all have a nearly identical genetic structure (5′ untranslated region, intron-exon size and organization), and the catalytic triad of serine proteases is conserved by all members, with the histidine always occurring near the end of the second exon, the aspartate in the middle of the third exon, and the serine residue at the beginning of the fifth exon. All kallikreins are produced as prepropeptides with a 17 to 20 amino acid signal sequence and a 4 to 9 amino acid activation peptide. They also contain 10 to 12 conserved cysteines that form five to six disulfide bonds. Finally, most if not all genes are under steroid hormone control.

Kallikreins are expressed in a wide variety of tissue including prostate, breast, ovary, and testis.[252] For example, KLK3 (PSA) is highly expressed in prostate and is discussed in detail later in the chapter. KLK3 also has minor expression in breast, thyroid, salivary glands, lung, and trachea, and KLK11 and KLK12 are highly expressed in more than 10 tissues, with minor expression in at least four others.

Only three of the 15 kallikreins have been assigned a specific biological role. The major biological role of hK1 is the release of lysyl-bradykinin (kallidin) from low molecular weight kininogen; however it has been implicated in the processing of peptide hormones, including proinsulin, low-density lipoprotein (LDL), prorenin, the precursor of atrial natriuretic peptide, and vasoactive intestinal peptide. The role of hK2 has only recently been investigated. Seminal plasma hK2 cleaves seminogelin I and II, but at different sites than hK3 (PSA). Furthermore, a role for hK2 in the regulation of growth factors through the proteolysis of insulin-like growth factor binding protein 3 (IGFBP-3) has been suggested. hK3, also known as PSA, is not only found in prostate tissue (discussed below), but is found in relatively high concentration in nipple aspirate fluid, breast cyst fluid, breast milk, amniotic fluid, and tumor extracts.[23] Its presence in these fluids and tissue suggests a biological function in breast and a possible role in fetal development; however no specific function in these tissue has been identified to date.

Clinical Applications

The role of kallikreins as tumor markers is rather varied; a number of kallikreins have been associated with hormonal malignancies (prostate, breast, testicular, and ovarian cancers). The roles of hK3 (PSA) and hK2 are discussed in detail below. hK6 has been used as a serum marker for diagnosis, prognosis, and monitoring of ovarian cancer,[60] and as a cytosolic marker for prognosis of breast cancer. Serum hK5, hK6, hK10 and hK11 have also been used for diagnosis and monitoring of ovarian cancer[112,137,253,254] and high concentration of cytosolic hK10 in ovarian tumor and breast cells is a poor prognostic marker.[135,136] Kallikrein gene expression is associated with both positive and negative prognosis in various cancers, including prostate, ovarian, and breast cancers. For a review see reference 61.

Analytical Methodology

Reverse transcription-polymerase chain reaction (RT-PCR), northern and western blotting, and immunoassays have been used for detection of kallerin mRNA and protein in tissue extracts of ovarian, breast, testicular, and prostate tumors. Immunohistochemical techniques have been used for the detection of KLK7 in ovarian tumors and KLK10 in ovarian and testicular tumors. The serum levels of KLK3 (PSA) and KLK11 are evaluated by immunoassay.

Prostate-Specific Antigen

PSA is one of the most promising tumor markers of this decade. It is one of the few organ-specific tumor markers. Prostate cancer is the leading cancer in older men. When detected early (organ confined), it is potentially curable by radical prostatectomy. Therefore early detection is important. The role of PSA in prostate cancer has been reviewed.[35,43,54,166]

PSA was discovered by Hara and colleagues in 1971.[89] They called this seminal plasma protein γ-*seminoprotein*. Li and Beling isolated the same protein from seminal plasma and called it "protein E1" because it has a slow β-mobility in electrophoresis and a molecular weight (MW) of 31,000. In 1978 Sensabaugh characterized this glycoprotein with isoelectric points between 6.5 and 8.0 and called it "p30." In 1979 Wang and co-workers purified a protein from prostatic tissue and called it *prostate-specific antigen*. PSA is found in normal, benign, hyperplastic, and malignant prostatic tissues. γ-seminoprotein, p30, and PSA are biochemically very similar.

Biochemistry

PSA is a single-chain glycoprotein that is 7% carbohydrate. It has 237 amino acid residues and four carbohydrate side chains with linkages at amino acid 45 (asparagine), 69 (serine), 70 (threonine), and 71 (serine). The N-terminal amino acid is isoleucine, and the C-terminal residue is proline. Its MW is 28,430,[16] and it has isoelectric points from 6.8 to 7.2 because of its various isoforms. The three-dimensional structure and the antigenic domain of PSA have been characterized.[46]

The complete gene encoding PSA has been sequenced and located on chromosome 19.[59,134] It is similar to the kallikrein-1 gene with 82% homology. Functionally, PSA is a serine protease of the kallikrein family. It is produced exclusively by the epithelial cells of the acini and ducts of the prostate gland. PSA is secreted into the lumina of the prostatic duct. In the seminal fluid, PSA cleaves a seminal vesicle–specific protein into several low molecular weight proteins as part of the process of liquefaction of the seminal coagulum. Therefore PSA possesses chymotrypsin-like and trypsin-like activity. Autodigestion of PSA has been reported at three possible locations—*LYS* 148, *LYS* 185, and *ARG* 85. The addition of

protease inhibitors may be important to prevent the autohydrolysis of PSA in solution.[46]

Molecular Forms of Prostate-Specific Antigen

PSA exists in two major forms in blood circulation. The majority of PSA is complexed with protease inhibitor α_1-antichymotrypsin (ACT) (MW 100,000) or with α_2-macroglobulin (AMG) and a minor component of free PSA (MW 28,430). Most immunoassays measure both free and ACT-complexed PSA but not AMG-PSA.[126,226] In human seminal fluid, PSA could be fractionated into five isoforms. PSA-A and PSA-B are active, intact enzymes capable of forming complexation with ACT. PSA-C, PSA-D, and PSA-E are nicked forms with disulfide bonds cleaved; they possess low or no enzymatic activities.[262] The inactive forms of free PSA are composed of three distinct molecular forms—bPSA, pPSA, and iPSA. bPSA in tissue is relatively localized in the transition zone of the prostate and contributes to fPSA in BPH serum. pPSA is localized in the peripheral zone of the prostate and contributes to fPSA in cancer serum.[146,212]

Physiological Properties

The metabolic clearance rate of PSA follows a two-compartment model with initial half-lives of 1.2 and 0.75 hours for free PSA and total PSA and subsequent half-lives of 22 and 33 hours.[168] Because of this relatively long half-life, 2 to 3 weeks may be necessary for the serum PSA to return to baseline levels after certain procedures, including transrectal biopsy, transrectal ultrasonography, transurethral resection of the prostate, and radical prostatectomy. Prostatitis and acute urinary retention can also elevate PSA concentration. Although the digital rectal examination has no clinically important effects on serum PSA levels in most patients, in some it may lead to a twofold elevation.

There appears to be significant physiological variation of serum PSA levels (up to 30%). Serum PSA has been reported to be decreased by 18% after the patient has been hospitalized for 24 hours. The reason for this reduction is not known. It may be that patients become sedentary (e.g., remain in the supine position) or suspend sexual activity. It is perhaps a good practice to collect serum samples from ambulatory patients.

Nonprostatic PSA

Originally, it was thought that PSA was solely expressed in prostate tissue. However, it was later found that PSA also is expressed in numerous tissues, most notably hormonally regulated tissue. It should not be surprising that PSA is expressed in these tissues as its promoter contains three androgen response elements and can be activated by androgens, progestins, and glucocorticoids. The presence of PSA in breast tissue is related to progesterone and estrogen receptor positivity and correlates with a favorable prognosis[256,257] but surprisingly, with resistance to tamoxifen therapy.[72] PSA positivity was found to be significantly associated with smaller tumors, steroid receptor positivity, low cellularity, diploid tumors, low S-phase fraction, less advanced disease, and longer survival. PSA has also been measured in nipple aspirate fluid (NAF) as a possible tool for breast cancer risk assessment.[191] Women with no risk factors had relatively high NAF PSA, and women with breast cancer had overall lower NAF PSA measurements.

Clinical Applications

PSA is an extremely useful tumor marker for prostate cancer. It is used to detect and stage the cancer and to monitor treatment of prostate cancer. It is also thought to be involved in tumor progression.

Early Detection of Prostate Cancer

PSA testing by itself is not effective in the screening or detection of early prostate cancer because PSA is specific for prostatic tissue but not for prostatic cancer. BPH is a common disease in men 50 years of age and older. Studies have shown that the PSA values in patients with BPH are similar yet statistically different from those associated with early prostatic cancer (i.e., those of patients with organ-confined cancer).[157] Unfortunately the overlap of PSA values between these two groups is so extensive that selecting an optimum cut-off value of PSA, either 4 or 10 µg/L, is almost impossible. The use of serum PSA together with digital rectal examination and followed by transrectal ultrasonography provides more accurate and sensitive diagnosis than digital examination alone.[35]

The clinical sensitivity of PSA is 78% at a cut-off value of 4.0 µg/L. By lowering the cut-off value to 2.8 µg/L, sensitivity increases to 92%, whereas specificity decreases from 33% to 23%. Raising the cut-off value to 8 µg/L improves the specificity to 90%.[40] Using ROC analysis (see Figure 23-1), PSA is a better predictor than PAP for the diagnosis of prostatic cancer.[184]

To improve the ability of PSA testing to detect early prostate cancer, several approaches have been suggested. One approach is to use age-adjusted reference intervals: 0 to 2.5 µg/L for men ages 40 to 49 years, 0 to 3.5 µg/L for 50 to 59 years, 0 to 4.5 µg/L for 60 to 69 years, and 0 to 6.5 µg/L for 70 to 79 years. By lowering the upper limit of the reference interval, more cancer will be detected in younger men for whom a potential cure by radical prostatectomy is most beneficial.[158] Another approach is to use PSA density (i.e., divide PSA concentration by the prostatic volume as determined by transrectal ultrasonography).[18] Patients with PSA between 4 and 10 µg/L, a negative digital rectal examination result, and elevated PSA density have increased risk for prostate cancer. The third approach is using PSA velocity—the rate of PSA increase as a function of time. By establishing a baseline level of PSA in each patient, the rate of increase of PSA is then calculated. The increase of PSA in health, BPH, and prostatic cancer appears to be different, with the highest rate (greater than 0.75 µg/L/yr) observed in patients with prostate cancer.[33] The specificity improved to 90% for BPH, and sensitivity is 72% for prostate cancer. A 1996 study

of free PSA velocity found that percent free PSA is the earliest serum marker for predicting subsequent diagnosis of prostate cancer.[169]

The percent free PSA has been used to improve the sensitivity and specificity in detecting prostate cancer, particularly for patients in the diagnostic "gray" zone of PSA between 4 and 10 μg/L or 2 and 20 μg/L.[34,164] ProPSA (pPSA) has been reported to improve over fPSA in the detection of prostate cancer with total PSA in the 2.5 to 4.0 ng/mL range.[212] Complexed (cPSA) showed improved specificity over total PSA for prostate cancer detection in a multicenter clinical trial.[163]

In addition to the approaches described above, a number of algorithms using PSA and other analytes have been developed to increase the sensitivity of prostate cancer detection. They include logistic regression and artificial neural networks.

Logistic Regression. Logistic regression (LR) is a technique for making predictions when the dependent variable is a dichotomy (either the patient has cancer or does not), and the independent variables (PSA, f/T-PSA, age, etc.) are continuous and/or discrete. This technique is used to determine which variables (analytes) have the greatest predictive value in determining cancer risk, from which probability curves are generated. Finne et al used 758 men from a group of over 10,000 screened patients (200 confirmed prostate cancer and 558 controls) with total PSA between 4 and 20 μg/L to develop nomograms using total PSA, f/T-PSA, digital rectal examination, and prostate volume for determination of cancer probability.[69] The technique gave improved clinical sensitivity and specificity for cancer detection over total PSA and f/T-PSA and should reduce the number of biopsies performed and increase the detection rate of prostate cancer.

Artificial Neural Networks. Artificial neural networks are computer-based multiparameter techniques inspired by biological neurons, which operate as nonlinear summing devices. These networks have been applied to prostate cancer in determining which patients should undergo biopsy.[51,181,227,228] Unlike LR, neural networks must be trained, in much the same way that biological neural networks must be trained, to correctly categorize patients. The training involves selection of various inputs (total PSA, f/T-PSA, prostate volume, etc.) with known outcomes. Therefore selection of the correct training data set is extremely important. This technique can increase the sensitivity and specificity and the positive and negative predictive value obtained from prostate cancer screening; however care must be taken in training and validation of the neural network. An example is the ProstAsure Index.

The ProstAsure index, developed by Zhang, Stamey, and Chan,[12,221] was designed to increase the sensitivity and specificity of cancer detection, while maintaining a reasonable false positive detection rate. The index is derived from several values, including age, total PSA, creatine kinase isoenzymes, and prostatic acid phosphatase, which are input into a neural network–derived, nonlinear algorithmic procedure. The results are in the form of four zones (zones 1 to 4) based on an ascending probability of cancer. Patients in either zone 3 or 4 should be considered for biopsy. The algorithm performed well when compared with the free-total PSA ratio and had a sensitivity of 93%, with a specificity and apparent positive predictive value of 81% and 61%, respectively, compared with 80%, 74%, and 49%, respectively, for free-total PSA at the 15% threshold. At the 19% free-total PSA threshold, the sensitivity was increased to 93%, but the specificity and PPV decreased to 59% and 48%, respectively. However, the study by Babaian et al was on a limited number of patients and only tested its usefulness in the PSA range of less than or equal to 4 μg/L, not the 4 to 10 μg/L where the free-total PSA ratio is used.

Staging of Prostate Cancer

PSA has been found to correlate with clinical stages of prostate cancer.[222] Higher PSA levels and higher percentages of patients with elevated PSA concentrations are associated with advanced stages. However, PSA testing is not sufficiently reliable to determine stages on an individual basis.

PSA has also been found to correlate with pathological stages of tumor extension and metastases. Advanced pathological stages are associated with higher PSA levels in the serum. Patients with organ-confined disease seldom have a PSA level greater than 50 μg/L, suggesting that patients with these elevated levels are most likely to have extracapsular tumor extension. Because significant overlap occurs in PSA values among stages, PSA cannot be used to determine the pathological stage in a given individual. Therefore, PSA by itself should not be used to decide whether a patient has prostate cancer confined to the organ and therefore is a likely candidate for radical prostatectomy. The level of PSA can serve as a guide and is more useful in evaluating the presence of metastases. Patients with PSA levels less than 20 μg/L rarely have bone metastases. Studies have shown that PSA could replace the radionuclide bone scan in newly diagnosed untreated prostate cancer patients who have a low serum PSA concentration (less than 10 μg/L) and do not have symptoms relating to the skeletal system.[156]

Monitoring Treatment

The greatest clinical use of PSA is in the monitoring of definitive treatment of prostate cancer. This treatment includes radical prostatectomy, radiation therapy, and antiandrogen therapy. PSA has also been suggested to play a role in tumor progression.[55]

Radical Prostatectomy. This surgery removes all prostatic tissue. Because PSA is produced almost exclusively by the prostatic tissue, after radical prostatectomy the PSA level should fall below the detection limit of the assay. This may require 2 to 3 weeks owing to the 2- to 3-day half-life of PSA. If the half-life is longer than normal, it must be assumed that residual tumor is present.[157,222] For example, Walsh and

TABLE 23-7 Prostate-Specific Antigen and Tumor Status in 297 Men Followed 1 to 13 Years After Radical Prostatectomy

	Postoperative PSA Level			
		>0.5 µg/L		
Pathological Stage	<0.5 µg/L NED*	NED	Recurrence†	(%)
Organ confined	169	8	3	6
Capsular penetration	51	3	10	20
Seminal vesicle involvement	9	10	9	68
Positive lymph nodes	4	15	6	84
Total	233	36	28	

From Walsh PC, Oesterling JE, Epstein JI, et al. The value of prostate-specific antigen in the management of localized prostate cancer. In: Murphy G, Khoury S eds. Therapeutic progress in urological cancer. New York: Alan R Liss Inc, 1989:27-33.
*No evidence of disease.
†Local recurrence and/or metastatic disease.

co-workers[244] reported a long-term study of 297 men who were followed for 1 to 13 years after radical prostatectomy (Table 23-7). For the 180 patients with organ-confined cancer, only 11 (6%) showed elevated PSA levels (greater than 0.5 µg/L). Three of these patients had documented recurrence, whereas the other eight had no evidence of cancer. The frequency of elevated PSA levels increased with advancing pathological stage. Of the entire group, 12% had elevated PSA levels without evidence of recurrence. These patients most likely had residual disease. All patients with the recurrence of cancer had elevated PSA levels.

It is recommended that measurement of PSA be done every 3 months during the first year following surgery, every 4 months in the second year, and every 6 months thereafter. The clinical threshold of an elevated PSA varies with each institution and ranges from 0.1 to 0.3 µg/L. The clinical threshold will be affected by the test's analytical sensitivity and biological variation of serum PSA. In any case, an increasing PSA level after radical prostatectomy is a strong indication of disease recurrence. The time between PSA concentration elevation and clinical recurrence is between 1 and 5 years.

Radiation Therapy. The role of PSA in the monitoring of patients after definitive radiation therapy is less well defined as compared with that after radical prostatectomy. The majority of patients show an initial decrease of PSA level after radiation therapy. PSA is better than digital rectal examination for detecting residual cancer after radiation therapy.[202]

Antiandrogen Therapy. Antiandrogen therapy includes bilateral orchiectomy and treatment with luteinizing hormone-releasing hormone analogues, diethylstilbestrol, and flutamide. PSA testing is useful for predicting prognosis and monitoring treatment response to this type of therapy in patients with stage D2 prostate cancer. The level of PSA is inversely proportional to the survival time and increases with cancer progression, decreases in remission, and remains unchanged in stable disease. PSA could replace the radionuclide bone scan for monitoring patients with advanced disease.[47]

Androgen deprivation therapy may have a direct effect on the PSA level that is independent of the antitumor effect. The production of PSA may be under the influence of hormones such as dihydrotestosterone. Thus the PSA levels in patients who receive antiandrogen therapy may have a different meaning than they do in patients receiving other types of therapies.[156]

Tumor Progression

PSA has also been suggested to play a role in tumor progression.[55] PSA digests extracellular matrix proteins laminin and fibronectin that may promote metastasis. PSA also digests IGFBP-3, increasing the local concentration of insulin-like growth factors, which also may promote tumor growth.

Analytical Methodology

Both traditional and ultrasensitive assays are available for measuring PSA.

Traditional Assays

Immunoassays are used to measure PSA and are commercially available. Most of them use nonisotopic labels, such as enzyme, fluorescence, or chemiluminescence. The majority of these assays are automated on an immunoassay system. Different assays and even the same assay with different lots of reagent may produce different results. The reasons for such differences are due to changes in assay calibration, production lot variation, assay reaction time, reagent matrices, assay sensitivity, and imprecision. Antibodies react with different PSA epitopes; therefore, some antibodies react dissimilarly with the various molecular forms of PSA. Assays are classified as equimolar if they bind to free and cPSA equally and nonequimolar if they bind to free or cPSA differently. Examples of equimolar assays are the ACCESS

Hybritech PSA assay (Beckman Coulter, Brea, Calif.) and the TOSOH NexIA immunometric assay (which uses the same antibodies as the Access assay). The World Health Organization, the International Federation of Clinical Chemistry, and the National Committee for Clinical Laboratory Standards have developed two international preparations to facilitate the effort to standardize PSA assays: 100% free PSA (code 96/686) and 90% PSA-ACT complex and 10% free PSA (code 96/700).[44]

Ultrasensitive Assays

Ultrasensitive PSA is the term used for assays with detection limits of 0.01 to 0.001 μg/L, which are significantly less than that of traditional PSA assays.[68] The major use for ultrasensitive PSA is detection of residual prostate cancer after prostatectomy. After radical prostatectomy, circulating levels of PSA are extremely low; 80% have a PSA lower than 0.01 μg/L, and 20% have a PSA below 0.001 μg/L.[53,241,255] A postprostatectomy increase in PSA is associated with disease recurrence. Routine PSA methods cannot detect an increase in PSA until it reaches about 0.1 μg/L; however ultrasensitive methods can detect an increase long before traditional methods (1 to 2 years). This provides the opportunity for earlier treatment and an increased likelihood of a cure.

Ultrasensitive methods are also useful in measuring PSA in women, since normal PSA levels in women are less than or equal to 0.01 μg/L. An increased PSA in women is seen during pregnancy and in breast cancer patients.[24]

Human Glandular Kallikrein 2

Human kallikrein 2 (hK2) and PSA (human kallikrein 3) are serine proteases that share 80% identity in protein sequence[192] and are almost exclusively found in prostatic epithelium.

Biochemistry

Similar to PSA, hK2 concentrations are 100,000-fold higher in seminal fluid than in serum.[131] hK2 has the ability to form complexes with endogenous antiproteases. One important inhibitor is the protein-C-inhibitor (PCI) that is the major ligand complexed to hK2 in seminal fluid, but in vitro, hK2 also forms complexes with alpha$_2$-antiplasmin, alpha$_2$-macroglobulin, ACT, antithrombin III, C1-inactivator, and plasminogen activator inhibitor-1.[145] Gel filtration studies on a relatively low number of samples have suggested that hK2 mainly occurs in a free, noncomplexed form hK2 in serum, where only a minor proportion (5% to 20%) may be complexed with protease inhibitors. In vitro, recombinant hK2 activates proPSA into mature, catalytic active form.

Clinical Applications

Immunohistochemical studies demonstrated that tissue expression of hK2 showed intense staining in high-grade cancers and lymph node metastases, whereas it showed weaker staining for low-grade cancers and BPH.[50] Serum hK2 alone or hK2*total PSA/free PSA has been shown to be a significantly better predictor of pT2a/b-PCa than tPSA.[85] Recker et al confirmed the improvement in staging accuracy, noting that hK2 was the only serum analyte that significantly discriminated pT2a/b from greater than or equal to pT3a-PCa. Moreover, hK2 discriminated aggressive Grade 3 from less aggressive Grade 1 and Grade 2 PCa.[179]

Analytical Methodology

Currently, there are two major hK2 immunoassays. Hease and colleagues found notable differences in values measured by the two immunoassays for hK2 for identical patient samples.[86] Calibration of the two assays by use of a common, ek-rhK2-based calibrator revealed a substantial gain in agreement between the assays.

The Urokinase-Plasminogen Activator System

The urokinase-plasminogen activator system consists of three main components, urokinase-plasminogen activator (uPA, a 53 kDa serine protease), the uPA membrane-bound receptor (uPAR), and the uPA inhibitors, PAI-1 and PAI-2.[5,63,182,185]

Biochemistry

uPA is produced as a single inactive polypeptide, which is activated by cleavage between lysine 158 and isoleucine 159. The cleavage is catalyzed by a number of proteases, including cathepsins B and L and hK2. The active form of uPA consists of an A-chain, which interacts with its cell-surface receptor, uPAR, and a catalytically active B-chain. The most thoroughly characterized activity of uPA is the conversion of plasminogen to active plasmin, which degrades extracellular matrix (ECM) components and activates matrix metalloproteinases (MMPs), and that further degrade the ECM, and activate and release specific growth factors (fibroblast growth factor [FGF]2 and transforming growth factor [TGF]-β). The activity of uPA is controlled in vivo by two inhibitor molecules, PAI-1 and PAI-2. PAI-1 and PAI-2 not only act to inhibit uPA but also have a number of other functions, including angiogenesis, cell adhesion and migration, and inhibition of apoptosis.

Clinical Applications

uPA has been used as a prognostic marker in breast cancer and a number of other cancers.

Breast Cancer

uPA was the first protease implicated in metastasis evaluated for prognostic value in humans. At least 20 independent groups have demonstrated that breast cancer patients with high activity of uPA in their primary tumors have a worse disease-free pattern than those patients with low uPA activity.[62] The prognostic impact of uPA appears to be independent of other traditionally used markers, such as axillary node status, tumor size, grade, and estrogen receptor (ER) status. In most studies, uPA is a more potent predictor of overall survival than tumor size, grade, or ER

status, and equally powerful as nodal status. The patients who benefit most from uPA measurement are those who are newly diagnosed with histologically negative local nodes. The long-term survival of this group is 70% to 80% with local therapy alone, and no further benefit is gained from adjuvant chemotherapy. uPA may be able to detect the small number of patients most at risk for recurrent disease and spare other cured patients from unnecessary chemotherapy.

PAI-1 has also been associated with progression of breast cancer. Paradoxically, high levels of PAI-1 correlate with more aggressive disease. This appears to be because of the involvement of PAI-1 in angiogenesis and inhibition of apoptosis as opposed to inhibition of uPA. Recently a prospective study[101] of 674 node-negative breast cancer patients demonstrated that women with high levels of uPA and/or PAI-1 had a notably shorter disease-free period than those with low levels of both proteins. The level 1 evidence for the prognostic use of uPA and PAI-1 should allow these markers to enter routine use in breast cancer evaluation. Recently, reviews and metaanalysis studies suggested that uPA and PAI-1 are ready to be used as prognostic markers of breast cancer at the clinic.[90,130,261]

Other Cancers

uPA has also demonstrated its usefulness as a prognostic marker in colorectal cancer. In one study,[62] uPA was found to be a marker of disease outcome in patients with tumor invasion but negative node status (Dukes' B stage). High levels of uPA were also found to correlate with aggressive disease in both gastric and esophageal cancers. Preliminary studies have implicated uPA as a prognostic marker in ovarian, renal, hepatocellular, pancreatic, gliomas, urinary, bladder, adenocarcinoma of the lung, and cervical cancer. Thus uPA may function as a general prognostic marker in cancer.

Analytical Methodology

The original assay developed for uPA measured its catalytic activity. This assay has been replaced by enzyme-linked immunosorbent assay (ELISA) and a number of research and commercially available kits have been developed for detection of uPA and PAI-1. uPA and PAI-1 can be determined in serum and, more frequently, in tissue extracts. Since a proportion of uPA is bound to its receptor, the addition of Triton X-100 is required for full extraction of uPA, which is necessary to gain maximal prognostic information. Generally, increased levels of uPA and/or PAI-1 indicate poor prognosis. A uPA level below 3 ng/mg total tissue and PAI-1 below 14 ng/mg total tissue have a notably better prognosis.[101] Most studies showing a prognostic value for uPA have used ELISA for detection; however some were done using immunohistochemistry. Immunohistochemical detection is easier, and requires less tissue; however interpretation is subjective and only semiquantitative.

CATHEPSINS

The cathepsins are lysosomal proteases and cathepsin B, D, and L have been investigated for their role in tumor development and progression.

Biochemistry

Like other proteases, cathepsins are synthesized as high molecular weight precursors that require processing for activation. Cathepsin B (CB) is a thiol-dependent protease normally found in lysosomes, and is activated by cathepsin D (CD) and matrix metalloproteinases. Activated CB can in turn activate uPA and specific metalloproteinases. Cathepsin L (CL) is similar in specificity to that of CB; however, it has little activity toward small molecular substrates. Cathepsin D, like CB, is a lysosomal protease; however, CD belongs to the aspartyl group of proteases.

The expression and localization of CB appears to be altered in tumors relative to normal tissue. In tumor tissue, CB can be associated with the plasma membrane or secreted. Increased expression has been demonstrated in breast, colorectal, gastric, lung, and prostate tumors, carcinomas, gliomas, melanomas, and osteoclastomas, suggesting a link with tumor development and/or progression.[116] Altered localization of CB has also been seen in various tumor tissue, such as colon carcinomas, thyroid cancers, gliomas, and breast epithelial tumors. This altered expression and localization is thought to be involved in tissue invasion through ECM degradation and growth promotion. The ECM degradation occurs through activation of CB and other proteases, such as MMPs and uPA. In addition to ECM degradation, CB releases growth factors: basic fibroblast growth factor (bFGF), insulin-like growth factor-1 (IGF-1), epidermal growth factor (EGF), and TGF-β associated with the ECM.

Stromal cells were originally thought to be passive bystanders in tumor development; however, evidence suggests an active role. Increased expression of ECM proteases, including CB, has been demonstrated in stromal cells at the border between tumor cells and normal tissue. Expression of both CB and CD is up regulated by various growth factors (bFGF, EGF, IGF-1) and direct contact with tumor cells. This suggests that as tumor cells invade the stroma, the stromal cells are induced to participate directly in matrix degradation.[116] Therefore detection of CB in stromal cells and tumor cells may have prognostic value.

Clinical Applications

A limited number of studies have associated high levels of CB in multiple tumor types with aggressive disease. All, with one exception, are retrospective studies with low numbers of patients. In the one large study (n = 1500 patients), CB was shown to be an independent prognostic marker for both relapse-free and overall survival in breast cancer patients; however, it is not as good a marker as uPA.

The majority of data relating to the prognostic value of CD is in relation to breast cancer[183]; however, its usefulness in squamous cell carcinoma (SCC) of the head and neck,

hepatocellular carcinoma, and gastric adenocarcinoma has been investigated in limited studies. For breast cancer, a 1999 report containing 2810 patients confirmed the prognostic value of CD.[73] The authors, using an RIA to detect cytoplasmic CD in tumor tissue, showed that tumors with high CD had a notably poorer relapse-free survival than did those with low CD levels.

In contrast to RIA detection of CD in tissue extracts, immunohistochemical detection has led to conflicting results. Some investigators have reported significant association between immunohistochemically determined CD and a poor outcome, and others found no relationship. Possible reasons include differences in antibody specificity, different scoring systems to quantify CD staining levels, different cut-off points for discriminating high from low values, and different types of tissue: fresh versus formalin-fixed and paraffin-embedded.[59] Therefore the prognostic usefulness of CD in SCC and other malignancies needs further study to determine the utility of CD as an independent marker.

The use of CL as a prognostic indicator has been best studied in breast cancer. Most studies measured CL from tumor extracts and correlated high levels of CL with a decrease in relapse-free survival. CL appears to be an independent prognostic marker in both node-negative and node-positive breast cancer, especially when combined with other prognostic markers such as CB, CD, node status, and steroid hormone receptor status.

Analytical Methodology

The initial assays for detection of CB used chromogenic substrates containing an Arg-Arg sequence and 2-naphthylamide and 7-amino-4-methylcoumarin as chromophores. These early assays lacked specificity and were likely to have suffered from interference by endogenous inhibitors (e.g., cystatins and stefins). CB and CL are now measured by ELISA; however to date no comparison has been made with the older CB methods. Immunohistochemistry has also been used to detect CB in tissue; however no detailed evaluations have been conducted.

The majority of studies correlating CD with tumor progression and prognosis have used an immunoradiometric assay that detects both the proforms and mature forms of CD. This assay can be used to measure CD in tissue extract generated for detection of steroid hormone receptors. CD has also been measured by western blot, by immunohistochemistry, and by activity.

Matrix Metalloproteinases

Matrix metalloproteinases (MMP) are a family of 23 structurally related zinc-dependent endopeptidases capable of degrading components of the ECM.[159,216]

Biochemistry

Most MMPs are secreted as a zymogen, and activation involves removal of a 10 kDa amino-terminal domain. Once in the active form, their proteolytic activity is inhibited by tissue inhibitors known as tissue inhibitors of metalloproteinases (TIMPs). The MMPs have been functionally grouped into four subgroups, based on their ECM specificity: collagenases, gelatinases, stromelysins, and membrane MMPs.

Clinical Applications

MMPs are involved in a number of functions including tissue remodeling and wound repair; however, they have also been associated with tumor growth, invasion, and metastasis.[242] Direct evidence for the role of MMPs in the development and progression of tumors has been provided by mouse knockout studies in which mice lacking various MMPs showed reduced tumorigenesis and progression. Conversely, increased expression is associated with tumor aggressiveness and poor prognosis. Increased expression of MMP-2 and MMP-9 is associated with accelerated tumor progression in oral carcinoma, lung adenocarcinoma, and bladder, ovarian, and papillary thyroid carcinoma. Similarly, increased staining of MMP-3 and MMP-9 is seen in high-grade versus low-grade endometrial sarcoma. In esophageal carcinoma, MMP-7 expression correlates with tumor aggressiveness.

MMPs also act as predictors of recurrence or metastatic risk. High preoperative serum levels of MMP-2 or MMP-3 are predictive of recurrence in patients with advanced urothelial carcinoma. Furthermore, high levels of MMP-2 in ovarian tumor cells can predict tumor recurrence. The expression of certain MMPs is predictive of metastatic risk. For example, expression of MMP-1 is associated with lymph node metastasis in cervical and peritoneal metastasis in gastric cancer. MMP inhibition may be a therapeutic strategy for cancer.[159]

Analytical Methodology

Gelatin zymography is a technique commonly used to detect MMPs, such as MMP-2 and MMP-9. Zymography is an electrophoretic technique used to identify proteolytic activity in enzymes separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis under nonreducing conditions. The SDS is removed, allowing the MMPs to refold and subsequently digest gelatin at the position of the separated protein. This technique, although tedious, has the advantage of specifically detecting the active form of the protease. MMPs are also detected in tissue sections by immunohistochemistry using specific antibodies, and in tissue extracts and serum by immunoassay.

Tumor-Associated Trypsin Inhibitor

Tumor-associated trypsin inhibitor (TATI) is a 6 kDa trypsin inhibitor that was first identified from the urine of an ovarian cancer patient.

Biochemistry

TATI is identical to the previously identified pancreatic secretory trypsin inhibitor (PSTI), which is also known as

the Kazal inhibitor. TATI is strongly expressed by pancreatic acinar cells together with trypsinogen. It is secreted into the pancreatic juice where it constitutes 0.1% to 0.8% of the total protein. It is expressed at lower concentrations in other healthy tissue, such as the gastrointestinal and urogenital tracts, the gallbladder, biliary tract, kidney, lung, liver, and breast. TATI also acts as an acute phase reactant and is induced under strong inflammatory conditions, as would be expected as its promoter contains an IL-6 response element. TATI function in vivo is thought to protect against autodigestion of body tissue by trypsinogen secreted by the pancreas and other tissue. TATI is rapidly cleared from the circulation by the kidneys with a half-life of approximately 6 minutes. Therefore patients with renal disease can have extremely high serum levels of TATI (greater than 1000 µg/L).

Clinical Applications

Although pancreatitis, severe injury, and inflammation can all increase its levels, TATI can still function as a relatively good tumor marker for various cancers. In most cancers, the increase in TATI is due to tumor production; however, inflammation associated with tissue destruction contributes to the overall TATI increase. Serum and urine concentrations correlate well, but because of greater variation in urine, serum is preferred.

Increases in both serum and urine TATI are common in ovarian cancer. In mucinous ovarian cancers, approximately 45% of patients have increased TATI in stage I, and 90% to 100% have increases by stage IV.[225] Fifty-five percent to 60% of patients with late stage endometrial cancer have increased serum TATI; however, only 20% show an increase in early stages. TATI is increased in cervical cancer, but squamous cell carcinoma antigen (SCCA) and CEA are better markers.

TATI is also useful in gastrointestinal and urological cancers. As may be expected due to its pancreatic production, TATI is a useful marker for pancreatic cancer and is increased in 75% to 90% of patients. In gastric cancer, TATI is increased in 40% to 65% of patients and high preoperative values correlate with a poor prognosis. Patients with hepatocellular (60% to 80%) or biliary tract cancer (75% to 100%) show an increase in TATI. The clinical sensitivity of TATI in hepatocellular cancer is similar to that of AFP and is useful in AFP-negative cancers. Colorectal cancers also increase TATI, with approximately 34% to 74% of patients showing an increase. However, CEA is a better marker of disease. In bladder cancer, TATI has been shown to be more useful than other serum markers and is a strong prognostic indicator. In renal cell carcinoma, TATI is a more sensitive marker than CEA, CA 15-3, CA 125, and CA 19-9, and is useful in monitoring disease progression and after surgery.

Analytical Methodology

TATI in either serum or urine is routinely measured by radioimmunoassay. However, other detection methods have been developed that are used mainly for research purposes. The reference interval for TATI is 3 to 21 µg/L in serum, and is method dependent, as a method employing monoclonal antibodies gives a slightly lower reference interval (3.1 to 16 µg/L). Urine concentration is more variable, with a reference interval of 7 to 51 µg/L.

Telomerase

Telomeres are specialized structures at the termini of eukaryotic chromosomes.

Biochemistry

Telomeres are composed of hexanucleotide repeats (TTAGGG) that signal the end of a chromosome and inhibit the DNA repair mechanism from joining the ends of chromosomes together. They also appear to function as a mitotic clock, which records the replicative history and sets a finite life span for normal somatic cells. During each replication, cycle telomeric DNA is lost because of the inability of the replication machinery to overcome the loss of terminal RNA primers. However, expression of functional telomerase is a mechanism to overcome telomeric DNA loss in germline cells and stem cells. Telomerase is a ribonucleoprotein reverse transcriptase that elongates telomere ends using a segment of its own RNA as a template. Two main components are required for telomerase activity: human telomerase RNA (hTR), which contains the template for reverse transcription, and human telomerase reverse transcriptase (hTERT), which consists of the enzyme's catalytic subunit.

Telomerase is normally active during embryogenesis, but is repressed in most somatic cells before or shortly after birth. Germline cells, activated lymphocytes, and other immortal cells show no shortening of telomere length and possess telomerase activity. Thus tumor cells should also show telomerase activity that can act as a specific marker of transformation.

Clinical Applications

Telomerase activity has been detected in more than 80% of cancers, including lung, breast, pancreatic, bladder, and many other cancers; however, it does not seem to be necessary for cancer development.[96] Its activity does, however, correlate with tumor progression and prognosis.

The detection of telomerase activity or hTERT mRNA in excretion, secretion, brushings, and washings has been evaluated. In pancreatic secretion samples, which contain freshly exfoliated cells, detection of telomerase activity was encouraging for cancer detection. Telomerase activity was also found to be useful in distinguishing between adenoma and carcinoma in intraductal papillary-mucinous tumors, which can sometimes be difficult to diagnose. In bronchial brushing samples, the clinical sensitivity of cancer detection is below 70% and false-positive results are commonly encountered because of contamination with lymphocytes, which contain measurable telomerase activity. The measurement of telomerase is also expected to become a useful

marker in cervical cancer, since most cervical cancers express telomerase. In cancers such as non–small cell lung cancer, gastric cancer and neuroblastoma, and adenocarcinomas of the stomach and colon telomerase activity is up regulated during tumor progression and is useful in the evaluation of malignant grading and patient prognosis.

Analytical Methodology

The TRAP (telomeric repeat amplification protocol) assay is a widely used method for detection of telomerase activity. This technique measures the telomerase activity present in cell extracts. Briefly, cellular extract containing telomerase activity is incubated with a telomeric substrate (a short strand of DNA onto which the telomerase will attach the telomeric repeats) followed by polymerase chain reaction (PCR) amplification of the elongated telomere. Detection of the PCR product is by a number of methods, including gel electrophoresis, radiometric detection, ELISA, and real-time PCR detection.[188]

HORMONES

Hormones have been recognized as tumor markers for more than 50 years. The introduction of specific RIA methods for a particular hormone that has very little cross-reactivity with similar hormones made it possible to monitor the treatment of cancer patients.[244]

With the introduction and use of monoclonal antibodies, the measurement of hormones is now accurate and precise. The production of hormones in cancer involves two separate routes. First, the endocrine tissue that normally produces it can produce excess amounts of a hormone. Second, a hormone may be produced at a distant site by a non-endocrine tissue that normally does not produce the hormone. The latter condition is called *ectopic syndrome*. For example, the production of adrenocorticotropic hormone (ACTH) is normotopic by the pituitary and is ectopic by the small cell of the lung. Consequently, elevation of a given hormone is not diagnostic of a specific tumor, because a hormone may be produced by a variety of cancers.

Multiple endocrine neoplasia (MEN) syndromes (MEN-1, MEN-2A, and MEN-2B) are familial disorders inherited in an autosomal dominant fashion that are manifested by tumors arising from amine precursor uptake and decarboxylase (APUD) neuroendocrine tissues. These tissue synthesize a number of polypeptide hormones, such as ACTH, calcitonin, gastrin, glucagon, insulin, melanocyte-stimulating hormone, secretin, and vasoactive intestinal polypeptide. The frequency of hormone production correlates with the degree of embryological relationship of the cancer origin to other tissues in the APUD system. MEN-1 has been mapped to the long arm of chromosome 11 (11q13). Medullary thyroid carcinoma (MTC) that is part of MEN-2 has been mapped to chromosome 10.[211] Examples of hormones that are used as tumor markers are listed in Table 23-8. ACTH, calcitonin, and hCG are discussed in more detail below.

TABLE 23-8 Hormones as Tumor Markers

Hormone	Type of Cancer
ACTH	Cushing's syndrome, lung (small cell)
Antidiuretic hormone	Lung (small cell), adrenal cortex, pancreatic, duodenal
Bombesin	Lung (small cell)
Calcitonin	Medullary thyroid
Gastrin	Glucagonoma
Growth hormone	Pituitary adenoma, renal, lung
hCG	Embryonal, choriocarcinoma, testicular (nonseminomas)
Human placental lactogen	Trophoblastic, gonads, lung, breast
Neurophysins	Lung (small-cell)
Parathyroid hormone	Liver, renal, breast, lung, various
Prolactin	Pituitary adenoma, renal, lung
Vasoactive intestinal peptide	Pancreas, bronchogenic, pheochromocytoma, neuroblastoma

Adrenocorticotropic Hormone

ACTH is a polypeptide hormone with 39 amino acids and an MW of 4500 that is produced by the corticotropic cells of the anterior pituitary gland (see Chapter 50). In 1928 a patient was described having a small cell carcinoma of the lung who had the signs and symptoms of what is now known to be cortisol excess.[28] A small number of these carcinomas can produce pro-ACTH, the precursor to ACTH. This precursor has an MW of 22,000, a 5% bioactivity, and most of the immunoactivity of ACTH. Traditional RIA measures both the precursor and the hormone. One immunometric assay in use is specific for ACTH.

Elevated serum levels of ACTH could be the result of pituitary or ectopic production. A high level of ACTH (greater than 200 ng/L) is suggestive of ectopic origin. Failure of the dexamethasone suppression test is also indicative of ectopic production. About half of the ectopic production of ACTH is a result of small cell carcinoma of the lung. Other conditions that elevate ACTH levels have been reported, including pancreatic, breast, gastric, and colon cancer, and benign conditions, such as chronic obstructive pulmonary disease, mental depression, obesity, hypertension, diabetes mellitus, and stress. The value of ACTH in the monitoring of therapy is still unknown.[14]

Calcitonin

Calcitonin is a polypeptide with 32 amino acids, has an MW of about 3400, and is produced by the C cells of the thyroid.[11] Normally, calcitonin is secreted in response to increased serum calcium. It inhibits the release of calcium from bone

and thus lowers the serum calcium level. The serum half-life is about 12 minutes. The level in healthy individuals is less than 0.1 μg/L. An elevated level is usually associated with medullary carcinoma of the thyroid.

Calcitonin is most useful in the detection of familial medullary carcinoma of the thyroid, an autosomal dominant disorder. Asymptomatic family members of the affected patients benefit from screening with computed tomography because basal levels are increased in such people. Provocative testing with intravenous administration of calcium and pentagastrin also produces increased calcitonin levels. Microscopic or occult malignancy has been detected in patients having a negative radioisotopic scan and normal thyroid glands on physical examination.

Calcitonin levels appear to correlate with such indicators of extent of disease as tumor volume and tumor involvement in local and distant metastases. Calcitonin is useful for monitoring treatment and detecting the recurrence of disease.

Calcitonin levels are also elevated in some patients with carcinoid and cancer of the lung, breast, kidney, and liver. The usefulness of calcitonin as a tumor marker in these malignancies has not been proven. Calcitonin elevation has been reported in other nonmalignant conditions, such as pulmonary disease, pancreatitis, hyperparathyroidism, pernicious anemia, Paget's disease of bone, and pregnancy.

Human Chorionic Gonadotropin

Elevated human chorionic gonadotropin (hCG) levels are seen in pregnancy, trophoblastic diseases, and germ cell tumors. It is a useful tumor marker for tumors of the placenta (trophoblastic tumors) and some tumors of the testes. It is also useful for diagnosing and monitoring pregnancy (see Chapter 54 for a discussion of hCG and pregnancy).

Biochemistry

hCG is a glycoprotein secreted by the syncytiotrophoblastic cells of the normal placenta. hCG consists of two dissimilar α- and β-subunits. The α-subunit is common to several other hormones: luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). The β-subunit is unique to hCG, and the 28 to 30 amino acids comprising the carboxyl terminal are antigenically distinct. hCG has an MW of 45,000.[238] The upper reference limit in men and nonpregnant women is 5.0 IU/L.

The production of subunits of hCG is under separate genetic control. In early pregnancy, the free β-subunit is produced together with intact (a whole molecule of) hCG. In late pregnancy, the free α-subunit predominates. Differential production of the subunits has been observed in cancer patients. However, the number of patients who produce only the free subunit is very small. Most cancer patients produce both free β-subunits and intact molecules.

Clinical Applications

hCG is elevated in nearly all patients with trophoblastic tumors (greater than 1 million IU/L), in 70% of those with nonseminomatous testicular tumors, and less frequently in those with seminoma. Lower percentages of elevation have been reported in cases of melanoma and carcinoma of the breast, gastrointestinal tract, lung, and ovary, and in benign conditions, such as cirrhosis, duodenal ulcer, and inflammatory bowel disease.

Also, hCG is useful in identifying patients with trophoblastic tumors and, together with AFP, in detecting nonseminomatous testicular tumors. Levels of hCG correlate with the tumor volume and disease prognosis. The presence of hCG in seminoma may indicate the presence of choriocarcinoma. Because hCG does not cross the blood-brain barrier, the normal cerebrospinal fluid–to-serum ratio is 1:60. Higher levels in cerebrospinal fluid may indicate metastases to the brain. Furthermore, the response to therapy for patients with central nervous system metastasis may be indicated by monitoring the hCG level.

hCG is most useful for monitoring the treatment and the progression of trophoblastic disease.[20] Levels of hCG correlate with tumor volume. A patient with an initial hCG level of greater than 400,000 IU/L is considered at high risk for treatment failure. After surgical removal of the tumor, hCG level is expected to decline. The normal half-life of serum hCG is about 12 to 20 hours. Slowly decreasing or persistent levels of hCG may indicate the presence of residual disease. During chemotherapy, weekly hCG measurement is recommended. After remission is achieved, yearly hCG measurement is recommended to detect relapse. The detection limit of the assay is important, because any residual hCG activity may indicate the presence of a tumor. Specificity for the β-subunit of hCG is also a factor because low levels of cross-reactivity with LH or FSH can cause false-positive results.

Analytical Methodology

The measurement of serum hCG improved greatly in the 1970s. The assay specificity improved by using an antibody to the β-subunit of hCG that had little cross-reactivity with other glycoprotein hormones, LH, FSH, and TSH. Currently, most hCG assays use an immunometric ("sandwich") format. The hCG assay measures the intact (whole) molecule when an antibody for the α-subunit and an antibody for the β-subunit are used in the immunometric format. This type of assay does not measure free α- or β-subunits because free subunits cannot form a sandwich with both antibodies. The total β-hCG assay measures both the intact hCG and free β-subunits. As a tumor marker, a total β-hCG assay may be preferred, because cancer patients produce notable amounts of free β-subunit. None of the commercially available hCG assays have been approved by the Food and Drug Administration (FDA) for use as a tumor marker assay.

ONCOFETAL ANTIGENS

Oncofetal antigens are proteins produced during fetal life. These proteins are present in high concentration in the sera

TABLE 23-9 Oncofetal Antigens as Tumor Markers

Name	Nature	Type of Cancer
AFP	Glycoprotein, 70 kDa, 4% CHO	Hepatocellular, germ cell (nonseminoma)
β-Oncofetal antigen	80 kDa	Colon
Carcinofetal ferritin	Glycoprotein, 600 kDa	Liver
CEA	Glycoprotein, 22 kDa, 50% CHO	Colorectal, gastrointestinal, pancreatic, lung, breast
Pancreatic oncofetal	Glycoprotein, 40 kDa	Pancreatic
Squamous cell antigen	Glycoprotein, 44-48 kDa	Cervical, lung, skin, head and neck (squamous)
Tennessee antigen	Glycoprotein, 100 kDa	Colon, gastrointestinal, bladder
Tissue polypeptide antigen	Cytokeratins 8, 18, 19	Various (breast, colorectal, ovarian, bladder)

CHO, Carbohydrate.

of fetuses and decrease to low levels or disappear after birth. In cancer patients, these proteins reappear. The production of these proteins demonstrates that certain genes are reactivated as the result of the malignant transformation of cells.

The discovery of the oncofetal antigens AFP and CEA in the 1960s revolutionized the modern era of tumor markers. AFP was first found in the sera of mice with liver cancer[2] and later[234] in sera of humans with hepatocellular carcinoma. CEA was discovered in 1965 by Gold and Freeman and was known initially as the Gold "antigen."[80] Oncofetal antigens that have been used as tumor markers, including AFP and CEA, are listed in Table 23-9.

Alpha Fetoprotein

AFP is a marker for hepatocellular and germ cell (nonseminoma) carcinoma.[232]

Biochemistry

AFP is a glycoprotein with a molecular mass of 70 kDa. It consists of a single polypeptide chain and is 4% carbohydrate. AFP is synthesized in large quantities during embryonic development by the fetal yolk sac and liver. It is one of the major proteins in the fetal circulation, but its maximum concentration is about 10% that of albumin. AFP is closely related both genetically and structurally to albumin, having extensive homologies in amino acid sequence. The genes coding for both proteins have been localized to chromosome 4q. As albumin synthesis increases during later fetal development, AFP concentrations in fetal serum begin to decline. They finally reach the trace concentrations found in normal adults 18 months after birth.

For tumor-derived AFP, the composition of carbohydrate on AFP depends on the activity of saccharide transferase in the tumor cells. Differences in carbohydrate side chains on AFP may be determined by the binding of AFP to lectins, such as concanavalin A (Con A) and lens culinaris (LCA). Molecular variants of AFP can be separated into the liver type and the yolk sac type; they differ from each other in their carbohydrate moiety. The yolk sac type of AFP contains an additional sugar, N-acetylglycosamine; this blocks the Con A binding site on the AFP. Therefore the yolk sac type of AFP shows a high percentage (50% to 70%) of Con A nonreactive (CNR) fraction, whereas the liver type, which lacks this additional sugar, shows a low CNR fraction (10% to 20%).[42] LCA binds to the fucosylated form of the first core N-acetylglucose, which is present in both liver and yolk sac types of tumor-derived AFP but not in AFP generated by benign liver diseases.

Clinical Applications

The serum AFP level is less than 10 μg/L in healthy adults.[41] During pregnancy, maternal AFP levels increase from 12 weeks of gestation to a peak of about 500 μg/L during the third trimester. The fetal AFP reaches a peak of 2 g/L at 14 weeks and then declines to about 70 mg/L at term. The use of AFP for detecting fetuses with neural tube defects is discussed in Chapter 54. In addition to pregnancy, elevated levels of serum AFP are also associated with benign liver conditions, such as hepatitis and cirrhosis. Most patients with these benign diseases (95%) have AFP levels lower than 200 μg/L.

Except in the pregnant patient, AFP levels greater than 1000 μg/L are indicative of cancer. At these levels of AFP, about half of hepatocellular carcinomas may be detected. However, because the serum level of AFP correlates with the size of the tumor,[108] detection of hepatocellular carcinoma is more useful at the earlier stages, when the tumor is small enough to be resectable (less than 5 cm) than when the tumor is large. To detect small tumors, the cut-off level for AFP has to be set at a low level; a cut-off point of 10 to 20 μg/L has been recommended. However, at this level, hepatitis and cirrhosis must be considered as possible causes of elevation.

Screening for hepatocellular carcinoma has been attempted in high-incidence areas, such as Africa, China, Taiwan, Japan, and Alaska.[141] Initial large-scale screening in China using less sensitive techniques (e.g., agglutination and immunodiffusion, which have cut-off values of 400 to 1000 μg/L) was able to detect notable numbers of new cases

of this type of cancer. More sensitive immunoassay methods having cut-off values of 10 to 20 μg/L and ultrasonography have been used in Taiwan and Japan with better success in detecting hepatocellular carcinoma at earlier stages.

AFP is also useful for determining prognosis and in the monitoring of therapy for hepatocellular carcinoma.[108] The level of AFP is a prognostic indicator of survival. Elevated AFP levels (greater than 10 μg/L) and serum bilirubin levels of greater than 2 mg/dL are associated with shorter survival time.

The AFP level is a good indicator for monitoring therapy and the change in clinical status. Elevated AFP levels after surgery may indicate incomplete removal of the tumor or the presence of metastasis. Falling or rising AFP levels after therapy may determine the success or failure of the treatment regimen. A notable increase of AFP levels in patients considered free of metastatic tumor may indicate the development of metastasis.

AFP and hCG combined are useful in classifying and staging germ cell tumors. Germ cell tumors may be predominantly of one type of cell or may be a mixture of seminoma, yolk sac, choriocarcinomatous elements (embryonal carcinoma), or teratoma.[13] AFP is elevated in yolk sac tumors, whereas hCG is elevated in choriocarcinoma. Both are elevated in embryonal carcinoma. In seminomas, AFP is not elevated, whereas hCG is elevated in 10% to 30% of patients who have syncytiotrophoblastic cells in the tumor. Neither marker is elevated in teratoma. One or both of the markers are elevated in about 90% of patients with nonseminomatous testicular tumor. Elevations were found in fewer than 20% of patients with stage I disease, 50% to 80% with stage II disease, and 90% to 100% with stage III disease. These markers correlate with tumor volume and the prognosis of disease.

The combined use of both markers is also useful in monitoring patients with germ cell tumors: Elevation of either marker indicates recurrence of disease or development of metastasis. The success of chemotherapy can be assessed by calculating the decrease of the levels of both markers using the half-lives of AFP (5 days) and hCG (12 to 20 hours).

Analytical Methodology

Serum AFP can be determined by immunometric assay using either a radioactive or enzyme label (see Chapter 54). Automated immunoassay systems to measure AFP using these techniques are available. The detection limit of AFP immunoassay is about 1 to 2 μg/L.

Carcinoembryonic Antigen

CEA is a marker for colorectal, gastrointestinal, lung, and breast carcinoma. CEA was discovered by Gold and Freeman in 1965.[80] Rabbits were immunized with extracts of human colon cancer tissue, and the resultant antisera were absorbed with extracts of normal human colon. Some antisera reacted with the tumor extracts but not with the extracts of normal tissue. The antigen, which was also found in embryonic tissue, was named *carcinoembryonic antigen.*

Biochemistry

CEA is a glycoprotein with a molecular mass of 150 to 300 kDa; it contains 45% to 55% carbohydrate. It is a single polypeptide chain consisting of 641 amino acids, with lysine in the N-terminal position. The heterogeneity of CEA can be demonstrated by using isoelectric focusing to separate the variants.

CEA consists of a large family of related cell-surface glycoproteins. The CEA proteins are encoded by about 10 genes located on chromosome 19. Up to 36 different glycoproteins have been identified in the CEA family. The major proteins are CEA and nonspecific cross-reacting antigen (NCA).[99] The domain structure of CEA, NCA 50, and the heavy chain of the immunoglobulin IgG are very similar. Thus CEA is part of the immunoglobulin gene "superfamily."

Clinical Applications

The CEA level is elevated in a variety of cancers, such as colorectal (70%), lung (45%), gastric (50%), breast (40%), pancreatic (55%), ovarian (25%), and uterine (40%) carcinoma. Because of the elevations associated with benign disease (i.e., false-positive results) and the number of tumors that do not produce CEA (i.e., false-negative results), CEA testing should not be used for screening.[206]

CEA testing may be useful as an adjunct to clinical staging. Persistently elevated levels that are 5 to 10 times the upper reference limit strongly suggest the presence of colon cancer but may be associated with other cancers. In colon cancer, CEA levels correlate with the stage of the disease. CEA levels are elevated in 28% of patients with Dukes' stage A colorectal cancer and in 45% of those with stage B. The pretreatment CEA level is prognostic of the development of metastasis. A high level of CEA is associated with a greater likelihood of developing metastasis. Evidence suggests that CEA is a cellular adhesion molecule that may potentiate invasion and metastasis.[99]

After successful initial therapy, CEA levels decline. During remission, CEA levels are stable. Rising CEA values may indicate recurrence of disease. The lead time from CEA elevation to clinical recurrence is about 5 months. A repeat laparotomy can be performed to confirm the relapse, which is detected in 90% of cases. In the monitoring of metastatic colon cancer, CEA is useful in following patients throughout therapy and the clinical course of the disease.

CEA is also useful in monitoring breast, lung, gastric, and pancreatic carcinoma. In breast cancer, elevated CEA is associated with metastatic disease. Early or localized breast cancer does not show CEA elevation. CEA is most useful in monitoring metastatic breast cancer during therapy and for detecting the development of bone or lung metastasis. For breast cancer, CEA is being replaced by other more specific markers, such as CA 15-3. In lung cancer, CEA determination is helpful in diagnosing non–small cell lung carcinoma

(greater than 65% of patients have elevated CEA) and in monitoring lung cancer.

Analytical Methodology

As with AFP, most assays use the immunometric format for the determination of serum CEA. Polyclonal or monoclonal antibodies, or a combination of both types, have been used in CEA immunoassays.

In the healthy population, the upper limit of CEA is about 3 μg/L for nonsmokers and 5 μg/L for smokers. Because the level of CEA measured is method dependent, values should always be compared using the same method. When changing methods, all patients being monitored should be tested in parallel using both the old and new methods. CEA level is elevated in some patients having benign conditions, such as cirrhosis (45%), pulmonary emphysema (30%), rectal polyps (5%), benign breast disease (15%), and ulcerative colitis (15%).

CYTOKERATINS

The cytokeratins are a large group of approximately 20 proteins that make up the cytoskeletal intermediate filaments of epithelial cells and cells of epithelial origin. The cytokeratins can be grossly divided into two groups, type 1 being smaller and acidic and type 2 being larger and neutral to basic. The clinically useful members of this family are tissue polypeptide antigen (TPA), tissue polypeptide-specific antigen (TPS), and cytokeratin 19 fragments (CYFRA 21-1).

Tissue Polypeptide Antigen

The discovery of TPA preceded that of AFP and CEA, but TPA is not a specific tumor marker.[22] It was later found that TPA could be identified by antibodies that react with cytokeratins 8, 18, and 19. TPA is produced by both normal and cancerous cells. Elevated serum levels of TPA are related to the proliferation activity and turnover of cells, allowing it to be used as a proliferation marker.[155] In pregnancy, TPA increases throughout gestation. After pregnancy, the level returns to normal after 5 days. TPA is also elevated in inflammatory diseases and in cancer; thus it is not useful for diagnosis. In the monitoring of metastatic diseases, TPA is useful when combined with CEA and CA 15-3 in breast cancer, with CEA and CA 19-9 in colon cancer, and with CA 125 in ovarian cancer. TPA may be helpful in the differentiation of cholangiocarcinomas (in which TPA level is elevated) from hepatocellular carcinoma (in which TPA level is not elevated).

Tissue Polypeptide-Specific Antigen

TPS is actually an antigenic site on the TPA complex that is specifically recognized by the M3 monoclonal antibody. This epitope has been proposed as a specific marker of cell proliferation, and is detectable in serum using a specific radioimmunoassay. TPS appears to correlate with proliferation activity of lung tumors, irrespective of histology and tumor volume, with increasing TPS levels in increasing stages.[29] Elevated levels of TPS correlate with a poorer outcome as assessed by univariate analysis.

Cytokeratin 19 Fragments

CYFRA 21-1 is elevated in all types of lung cancer, although it is most sensitive for non–small cell lung cancer and SCC. Levels of CYFRA 21-1 positively correlate with increasing stage and are useful in monitoring of disease course, and in postsurgical follow-up. In one study of non–small cell lung cancer patients, CYFRA 21-1 was shown to independently correlate with decreased survival, nodal status, and tumor stage, confirming its utility as a lung tumor marker.[176]

Squamous Cell Carcinoma Antigen

As its name implies, SCCA is useful in monitoring a wide variety of SCCs.

Biochemistry

SCCA is a glycoprotein previously referred to as "tumor-associated antigen 4." Subfractions of SCCA have been separated by isoelectric focusing into neutral and acidic fractions. The molecular weights range from 42,000 to 48,000. Both malignant and nonmalignant squamous cells have been shown to contain the neutral fraction, whereas the acidic fraction is found mainly in malignant cells. The acidic fraction is the one released into the blood circulation. The expression of SCCA appears to correlate with the grade of differentiation of SCCs.[107]

Clinical Applications

SCCA is elevated in a variety of SCCs, including those of the cervix, lung, skin, head, neck, digestive tract, ovaries, and urogenital tract. In general, the level of SCCA is proportional to the advancing stages of cancer. Screening is not effective, since only a small percentage of patients with early stages of cancer show elevated SCCA values. High pretreatment SCCA values appear to be associated with a poor prognosis. SCCA is useful in detecting the recurrence of cancer and in the monitoring of treatment and disease progression.[107]

Analytical Methodology

SCC antigen is measured using immunoradiometric assay or the microparticle enzyme immunoassay on the IMx analyzer (Abbott Diagnostics, Chicago). Healthy, nonpregnant women have SCC antigen values below 1.5 μg/L. Serum SCC antigen levels may be elevated (greater than 1.5 μg/L) in certain benign conditions, including pulmonary infection, skin disease, renal failure, and liver disease. It is also present in saliva, sweat, and respiratory secretions. Because of this, masks should be worn by laboratory personnel when analyzing SCC antigen.

TABLE 23-10 Mucin Tumor Markers

Name	Antigen and Source	Antibody	Type of Cancer
CA 125	Glycoprotein, >200 kDa, OVCA 433	OC 125	Ovarian, endometrial
Episialin			
CA 15-3	Glycoprotein, 400 kDa, membrane-enriched BrCa	DF3 and 115D8	Breast, ovarian
CA 549	High-MW glycoprotein	BC4E549, BC4N154	Breast, ovarian
CA 27.29	High-MW glycoprotein	B27.29	Breast
MCA	350-kDa glycoprotein	b-12	Breast, ovarian
DU-PAN-2	Mucin, 1000-kDa peptide epitope	DU-PAN-2	Pancreatic, ovarian, gastrointestinal, lung

MW, Molecular weight.

TABLE 23-11 Blood Group Antigen-Related Cancer Markers

Name	Antigen and Source	Antibody	Type of Cancer
CA 19-9	Sialylated Le^{xa}, SW-1116 colon CA	19-9	Pancreatic, gastrointestinal, hepatic
CA 19-5	Le^a and sialylated Le^{ag}	19-5	Gastrointestinal, pancreatic, ovarian
CA 50	Sialylated Le^a and afucosyl form	C50	Pancreatic, gastrointestinal, colon
CA 72-4	Sialylated Tn	B27.3, cc49	Ovarian, breast, gastrointestinal, colon
CA 242	Sialylated CHO	C242	Gastrointestinal, pancreatic

CARBOHYDRATE MARKERS

Carbohydrate-related tumor markers either are (1) antigens on the tumor cell surface or (2) secreted by the tumor cells.[87,88,198] Monoclonal antibodies have been developed against these antigens. These markers have been found to be clinically useful as tumor markers and tend to be more specific than naturally secreted markers, such as enzymes and hormones. Biochemically, they are high molecular weight mucins (Table 23-10) or blood group antigens (Table 23-11).

CA 15-3, CA 549, and CA 27.29 assays detect a high molecular weight glycoprotein mucin expressed by the mammary epithelium, known as *episialin*. The circulating episialin antigen is a heterogeneous molecule. CA 15-3, CA 549, and CA 27.29 assays detect similar yet different epitopes on the episialin. The main differences are the antibodies used for detection. They are used as markers for breast carcinoma.

CA 15-3

CA 15-3 is a marker for breast carcinoma.

Biochemistry

CA 15-3 is detected by a murine monoclonal antibody (MAb) DF3 produced against a membrane-enriched extract of a human breast cancer metastatic to liver. Another monoclonal antibody, 115D8, was developed against human milk fat globule membrane. The circulating DF3-reactive antigen is a heterogeneous molecule with a molecular mass of 300 to 450 kDa. The gene for this molecule is located on chromosome 1q. cDNA cloning indicates that the DF3 peptide core consists of a highly conserved 60-bp tandem repeat sequence. The polymorphism of the antigen is the result of different numbers of repeats in the peptide core. The DF3 antibody recognizes the epitope within this 20 amino acid–repeating sequence of the peptide core. The recognition of the epitope is also affected by glycation.[93]

Clinical Applications

In healthy subjects, the upper limit of CA 15-3 concentration is 25 kU/L. At this level, 5.5% of 1050 normal subjects, 23% of patients with primary breast cancer, and 69% of those with metastatic breast cancer show elevated CA 15-3 levels.[93] Elevated CA 15-3 levels are also found in other malignancies, including pancreatic (80%), lung (71%), breast (69%), ovarian (64%), colorectal (63%), and liver (28%) cancer. It is also reported to be elevated in benign diseases, although with less frequency (e.g., in benign liver [42%] and benign breast diseases [16%]).

CA 15-3 should not be used to diagnose primary breast cancer, because the incidence of elevation (23%) is fairly low. CA 15-3 is most useful in monitoring therapy and disease progression in metastatic breast cancer patients. A significant change must be at least 25% and correlates with disease progression in 90% of patients, with its regression in 78%. No change correlates with disease stability in 60%. CA 15-3

could replace CEA in metastatic breast cancer owing to its sensitivity and specificity.

Analytical Methodology

Two antibodies are used in immunoassays. The MAb 115D8 is attached to a solid support, whereas MAb DF3 is labeled.

CA 549

CA 549 is a marker for breast carcinoma.

Biochemistry

CA 549 is an acidic glycoprotein with an isoelectric point of pH 5.2. By sodium dodecyl sulfate/polyacrylamide gel electrophoresis under reducing conditions, CA 549 can be separated into two species with molecular masses of 400 and 512 kDa. One monoclonal antibody, a murine IgG_1 termed *BC4E 549*, was raised by immunizing mice with partially purified membrane preparations from T417 human breast tumor cell line. The other antibody, *BC4N 154* (a murine IgM), was developed against human milk fat globule membranes.[27]

Clinical Application

In a population of healthy women, 95% of the population has CA 549 values below 11 kU/L. Pregnancy and benign breast disease show minimum elevation. Some patients with benign liver disease show a slight elevation (see Table 23-4). CA 549 has been shown to be elevated in a variety of non-breast metastatic carcinomas, including ovarian (50%), prostate (40%), and lung (33%) carcinomas.

Similar to CA 15-3, CA 549 is not useful in detecting early breast carcinoma, because the proportion of patients with elevated CA 549 levels is low. Using ROC analysis, CA 549 is better than CEA at identifying active breast cancer (see Figure 23-2).[37] CA 549 is useful in detecting recurrence of breast cancer in patients after initial therapy followed by adjuvant therapy. An increasing CA 549 value after an initial decrease or stabilization indicates the development of metastases (see Figure 23-3). In the monitoring of advanced breast cancer patients, CA 549 correlates with disease progression and regression and helps detect metastases.[37,38]

CA 27.29

CA 27.29 is a marker for breast carcinoma.

Biochemistry

CA 27.29 is detected by a monoclonal antibody, B27.29, that is produced against an antigen in ascites of patients with metastatic breast carcinoma. The minimum epitope to which B27.29 reacts is the 8 amino acid sequence (SAPDTRPA) within the 20 amino acid tandem repeating sequence of the mucin core. The reactive sequence of the B27.29 overlaps with the sequence of DF3 used in the CA 15-3 assay. In inhibition studies using labeled MAb, B27.29 effectively competes with DF3 for binding to both CA 27.29 and CA 15-3 antigens.[180]

Clinical Applications

CA 27.29 has been approved by the FDA for clinical use in the detection of recurrent breast cancer in patients with stage II or stage III disease. In a multicenter study over a 2-year period monitoring 166 breast cancer patients, 26 patients developed recurrent disease. When two consecutive CA 27.29 antigen test results above 37.7 kU/L (99th percentile) were considered positive, the CA 27.29 assay had a sensitivity of 57.7%, specificity of 97.9%, positive predictive value of 83.3%, and negative predictive value of 92.6% for the detection of recurrent breast cancer. The performance appeared to be better than that of CA 15-3 in detecting patients with recurrent breast cancer.[39] In a group of metastatic breast cancer patients, CA 27.29 and CA15.3 showed similar clinical performances.[49]

Analytical Methodology

CA 27.29 is measured using a solid-phase competitive immunoassay. A prediluted sample is added to a polystyrene tube coated with B27.29 antigen and incubated with the ^{125}I-labeled murine antibody for B27.29. A calibration curve is constructed using five calibrators from 0 to 200 kU/L.

Mucinlike Carcinoma-Associated Antigen

Mucinlike carcinoma-associated antigen (MCA) is a marker for breast carcinoma.[25]

Biochemistry

MCA was identified on the surface of a breast carcinoma cell line by the monoclonal antibody b-12. MCA is a glycoprotein with a molecular mass of 350 kDa. The epitopes on this molecule are also recognized by DF3 and 115D8 antibodies of the CA 15-3 assay.

Clinical Applications

In a study of 100 healthy women, the upper reference limit for MCA was found to be 14 kU/L. MCA levels increase throughout pregnancy. In contrast, CA 15-3 only increases slightly during pregnancy. MCA level is elevated in 60% of metastatic breast cancer patients. However, elevated levels are also found in ovarian, cervical, endometrial, and prostate carcinoma. Minimum elevation is observed in benign breast disease. MCA levels correlate with CA 15-3 levels but not with CEA levels. In the monitoring of metastatic breast cancer patients, changes in MCA levels parallel those of CA 15-3 levels.

CA 125

CA 125 is a marker for ovarian cancer.[201]

Biochemistry

CA 125 is a high molecular mass (greater than 200 kDa) glycoprotein recognized by the monoclonal antibody OC 125. It contains 24% carbohydrate and is expressed by epithelial ovarian tumors and other pathological and normal tissues

of müllerian duct origin. The physiological function is unknown.

Bast and associates developed the MAb OC 125 using a cell line (OVCA 433) from a patient with a serous papillary cystadenocarcinoma of the ovary.[113] The OC 125 clone was selected for its reactivity with the OVCA 433 cell line and for its lack of reactivity with a B-lymphocyte line from the same patient.

Clinical Applications

In a healthy population, the upper limit of CA 125 level is 35 kU/L. CA 125 is elevated in nonovarian carcinoma, including endometrial, pancreatic, lung, breast, and colorectal and other gastrointestinal tumors. CA 125 is useful for determining the prognosis of endometrial carcinoma. It is also elevated in women in the follicular phase of the menstrual cycle and in benign conditions such as cirrhosis, hepatitis, endometriosis, pericarditis, and early pregnancy. CA 125 may be useful in the evaluation of the disease status in patients with advanced endometriosis but is not useful in screening for ovarian cancer in asymptomatic populations.[100] It cannot be used to differentiate ovarian cancer from other malignancies.

In ovarian carcinoma, CA 125 is elevated in 50% of patients with stage I disease, 90% with stage II, and more than 90% with stages III and IV. The level of CA 125 correlates with tumor size and staging. CA 125 is also useful in differentiating benign from malignant disease in patients with palpable ovarian masses. This differentiation is important because surgical intervention for malignant ovarian masses is far more extensive than that for the benign masses. Einhorn and colleagues studied 100 patients undergoing diagnostic laparotomy for palpable adnexal masses; of these, 23 were found to have a malignancy.[64] Using 35 kU/L as the cut-off value, the predictive values for malignant disease were 78% sensitivity, 95% specificity, 82% positive predictive value, and 91% negative predictive value. Tumor differentiation does not affect the CA 125 level.

A preoperative CA 125 level of less than 65 kU/L is associated with a significantly greater 5-year survival rate (42%) than is a level greater than 65 kU/L (5%). Postoperative CA 125 levels and the rate of decline are also predictors of survival. The half-life of CA 125 is normally 4.8 days. A group of patients with a CA 125 half-life of 22 days responded poorly to chemotherapy as compared with another group with a CA 125 half-life of 9 days.

CA 125 is useful in detecting residual disease in cancer patients following initial therapy. The sensitivity of CA 125 for detecting tumors before repeat laparotomy is 50%, and the specificity is 96%. After chemotherapy, the CA 125 level provides an indication of disease prognosis. A decrease in the CA 125 level by a factor of 10 after the first cycle of chemotherapy is indicative of improvement. Persistent elevation of CA 125 levels after three cycles of chemotherapy indicates a poor prognosis.

In the detection of recurrent metastasis, use of CA 125 level as an indicator is about 75% accurate. The lead time from CA 125 elevation to clinically detectable recurrence is about 3 to 4 months. CA 125 correlates with disease progression or regression in 80% to 90% of cases.[100]

Analytical Methodology

An immunoradiometric assay for CA 125 was first developed and manufactured by Centocor, Inc, now Fujirebio Diagnostics. A second generation assay (CA 125II) uses a monoclonal antibody, M11, as the capture and OC 125 as the conjugate. This assay has been approved by the FDA for the quantitative measurement of CA 125 in serum of women with primary epithelial invasive ovarian cancer.

Other Ovarian Cancer Biomarkers

A number of other potential ovarian cancer biomarkers have been discovered by using microarray technologies and other methods. The role of kallikreins as potential ovarian cancer biomarkers has already been described.* Some of the newly discovered biomarkers include mesothelin, HE4 protein, prostasin, osteopontin, and other carbohydrate antigens that were found to be elevated in a small proportion of ovarian cancers (e.g., CA 19-9, CA 15-3, etc.).[94,147,237] There is now a general trend for combining multiple biomarkers, including CA 125, to increase the sensitivity of detecting ovarian cancer, especially in screening settings.[97,142] Others have proposed the rate of increase of CA 125 as an effective screening tool.[209] The combined use of serum markers along with transvaginal ultrasonography generally increases the sensitivity in ovarian cancer screening programs but compromises specificity. The use of biochemical markers as panels in ovarian cancer screening is still under investigation.

DU-PAN-2

DU-PAN-2 is a marker for pancreatic cancer.[143]

Biochemistry

The epitope recognized by the antibody DU-PAN-2 is a mucin. Its molecular mass is between 100 and 500 kDa, and it is 80% carbohydrate. cDNA for the core protein has been cloned and sequenced, and the predicted amino acid sequence reveals a protein of 126 kDa containing 1295 amino acid residues with 42 tandem repeats. DU-PAN-2 antigen is found mainly in the glandular epithelia of the pancreatic and biliary systems and in the breast and bronchial ducts. A lower level of expression is found in cells of the salivary glands, stomach, colon, and intestine.[143]

Clinical Applications

Serum DU-PAN-2 levels are elevated in patients with pancreatic (54% to 61%), biliary tract (44% to 47%), and

*References 60, 112, 136, 137, 253, 254.

hepatocellular (44%) carcinomas. Comparative studies between DU-PAN-2 and CA 19-9 levels in pancreatic cancer show similar elevations in 70% to 80% of patients. The correlation of patient values for DU-PAN-2 and CA 19-9 was good except in patients who are Le^{a-b-} and therefore do not express CA 19-9.

Analytical Methodology

An RIA assay was developed by Metzgar and co-workers,[143] and an immunoenzymetric assay was developed by Kyowa Medex (Tokyo). The serum concentration of DU-PAN-2 in a healthy population is less than 100 kU/L. The cut-off level used to differentiate the presence of cancer from health is 300 or 400 kU/L.

BLOOD GROUP ANTIGENS

Blood group carbohydrates identified by monoclonal antibodies that have been used as markers of cancers are listed in Table 23-11. These include CA 19-9 (sialylated Le^{xa}), CA 50 (sialylated Le^{x-1}, afucosyl forms), CA 72-4 (sialyl Tn), and CA 242 (sialylated carbohydrate coexpressed with CA 50).

CA 19-9

CA 19-9 is a marker for both colorectal and pancreatic carcinoma.[120] CA 19-9 has been approved by the FDA for the quantitative measurement in serum and as an aid in monitoring pancreatic cancer patients.

Biochemistry

This carbohydrate antigen is a glycolipid—specifically, sialylated lacto-*N*-fucopenteose II ganglioside, that is a sialylated derivative of the Le^a blood group antigen and is denoted as Le^{xa}.The expression of the antigen requires the Lewis gene product, 1,4-fucosyl transferase. CA 19-9 is synthesized by normal human pancreatic and biliary ductular cells and by gastric, colon, endometrial, and salivary epithelia. In serum, it exists as a mucin, a high molecular mass (200 to 1000 kDa) glycoprotein complex. Patients who are genotypically Le^{a-b-} (about 5%) do not express CA 19-9. The monoclonal antibody against CA 19-9 was developed from a human colon carcinoma cell line, SW-1116.[117]

Clinical Applications

When using the Centocor CA 19-9 assay, the upper reference limit is 37 kU/L. Of 1500 healthy blood bank donors tested, 99% had CA 19-9 values below this limit. Elevated levels (greater than 37 kU/L) were seen in patients with pancreatic (80%), hepatobiliary (67%), gastric (40% to 50%), hepatocellular (30% to 50%), colorectal (30%), and breast (15%) cancer. Some patients (10% to 20%) with pancreatitis and other benign gastrointestinal diseases have elevated levels up to 120 kU/L. CA 19-9 levels correlate with pancreatic cancer staging. With the cut-off of 37 kU/L, 67% of patients with resectable and 87% of those with unresectable pancreatic cancer have elevated values. By raising the cut-off to 1000 kU/L, 35% of patients with unresectable tumors and only 5% of those with resectable tumors have elevated CA 19-9 values. CA 19-9 is useful in monitoring pancreatic and colorectal cancer. Elevated levels can indicate recurrence 1 to 7 months before detected by radiographs or clinical findings.[224] Unfortunately, early detection of relapse may not be useful because of the lack of effective therapy for pancreatic cancer.

Analytical Methodology

Several companies have produced CA 19-9 immunoassays. Typically, the CA 19-9 antibody is used both as the capture and the signal antibody.

CA 50

CA 50 is a marker for pancreatic and colorectal carcinoma.[87]

Biochemistry

CA 50 is a monoclonal antibody developed against the human colon adenocarcinoma cell line COLO 205. The CA 50 antibody recognizes an epitope on two carbohydrate moieties, sialosylfucosyllactotetraose (sialylated Le^a) and sialosyllactotetraose (sialylated Le^a lacking fucose). This antigen exists as a glycoprotein in serum and also as gangliosides in tissue. The sialylated Le^a is the predominant form of CA 50 in epithelial carcinoma and is also recognized by CA 19-9.

Clinical Applications

Elevated CA 50 levels have been reported in benign diseases of the pancreas (12% to 46%), biliary tract (35% to 38%), and liver (22% to 59%). In pancreatic cancer, 80% to 97% of patients have elevated levels. In colon cancer, elevated levels were reported in Dukes' A (19% to 43%), B (30% to 59%), C (53% to 73%), and D (53% to 73%) stages. In digestive tract carcinoma, elevated levels were seen in esophageal (41% to 71%), gastric (41% to 78%), biliary (58% to 70%), and hepatocellular (14% to 78%) cancer. Other malignancies were reported to have lower percentages of elevation, including breast, lung, renal, prostate, bladder, and ovarian cancer. Similar performances and good correlations were reported between CA 50 and CA 19-9 values.

Analytical Methodology

The original inhibition test has been replaced by an immunoradiometric assay and a time-resolved fluorescent immunoassay (the DELFIA method developed by Pharmacia, Uppsala, Sweden). The cut-off values for healthy subjects vary from 14 to 20 kU/L, depending on the method.

CA 72-4

CA 72-4 is a marker for carcinomas of the gastrointestinal tract and of the ovary.[194]

Biochemistry

B72.3 is a monoclonal antibody developed from the membrane-enriched fraction of breast carcinoma in a patient with liver metastasis. The B72.3 reactive antigen was purified and called TAG-72 (tumor-associated glycoprotein). Further purification of TAG-72 from LS-174T human colon carcinoma xenograft produced a new generation of monoclonal antibodies with higher affinity. These antibodies, denoted "cc" for "colon carcinoma," were used in subsequent studies.

Clinical Applications

A cut-off of 6 kU/L is used in the CA 72-4 assay. The following percentages of elevation were observed: in health, 3.5%; in benign gastrointestinal diseases, 6.7%; in gastrointestinal carcinoma, 40%; in lung cancer, 36%; and in ovarian cancer, 24%. A poor clinical correlation between CEA and CA 72-4 levels was found in gastric cancer. CEA and CA 72-4 values may be complementary. The plasma clearance of TAG-72 was studied by measuring serial TAG-72 values in patients with primary carcinoma of breast and with gastric, colorectal, and ovarian cancer. After removal of the tumor, the average time required for the level to decrease to 4 kU/L was 23.3 days. This suggests that TAG-72 may be useful in detecting residual tumor in these cancer patients.

Analytical Methodology

CA 72-4 is measured using an immunoradiometric assay (IRMA). It uses two monoclonal antibodies that were developed at the National Cancer Institute. B72.3 is the conjugate, whereas cc49 is the capture antibody. This IRMA is manufactured by Fujirebio Diagnostics.

CA 242

CA 242 is a marker for pancreatic and colorectal cancer.[119]

Biochemistry

CA 242 is a monoclonal antibody developed from a human colorectal carcinoma cell line, COLO 205. The antigenic determinant is a sialylated carbohydrate. CA 242 recognizes the epitopes of CA 50 and CA 19-9. CA 242 is found in the apical border of ductal cells of the human pancreas and in the epithelial and goblet cells of the colonic mucosa.

Clinical Applications

Using a cut-off value of 20 kU/L, elevated CA 242 values were found in 5% to 33% of patients with benign colon, gastric, hepatic, pancreatic, and biliary tract diseases; in 68% to 79% of patients with malignant pancreatic cancer; in 55% to 85% of patients with colorectal cancer; and in 44% of patients with gastric cancer. The correlation coefficients (R^2) of CA 242, CA 50, and CA 19-9 values in patients with colorectal, liver, pancreatic, and biliary tract disease ranged from 0.81 to 0.95. CA 242 and CEA appeared to have higher percentages of elevation in colorectal cancer than did CA 50 and CA 19-9. CA 242 seems to be less efficient than CA 19-9 or CA 50 in the detection of pancreatic cancer; however, this may depend on the cut-off value.

Analytical Methodology

An immunometric assay uses CA 50 antibody as the capture antibody and the CA 242 antibody as the conjugate. A fluoroimmunoassay for CA 242 is available as a DELFIA assay. The upper reference limit is 20 kU/L.

PROTEINS

Several proteins having tumor marker potential are listed in Table 23-12. Included in this group of tumor markers are proteins that are not enzymes, hormones, or high in carbohydrate content. Additional research is required to assess the clinical usefulness of most of these markers.

Immunoglobulin

Monoclonal immunoglobulin has been used as a marker for multiple myeloma for more than 100 years.[17] Monoclonal paraproteins appear as sharp bands in the globulin area of the serum electrophoretic patterns. More than 95% of

TABLE 23-12 Proteins as Tumor Markers

Name	Nature	Type of Cancer
β_2-Microglobulin	11 kDa	Multiple myeloma, B-cell lymphoma, chronic lymphocytic leukemia, Waldenström's macroglobulinemia
C-peptide	3.6 kDa	Insulinoma
Ferritin	450-kDa iron-binding protein	Liver, lung, breast, leukemia
Immunoglobulin	160-900 kDa, 3%-12% CHO	Multiple myeloma, lymphomas
Melanoma-associated antigen	90-240 kDa	Melanoma
Pancreas-associated antigen	100 kDa, 20% CHO	Pancreatic, stomach
Pregnancy-specific protein 1	10 kDa, 30% CHO	Trophoblastic, germ cell
Prothrombin precursor	Des-r-carboxy prothrombin	Hepatocellular
Tumor-associated trypsin inhibitor	6-kDa polypeptide	Lung, gastrointestinal, ovarian

patients with multiple myeloma have such an electrophoretic pattern. Appearance of nonmalignant monoclonal immunoglobulins increases with age, reaching 5% in patients older than 75 years. These nonmalignant monoclonal bands are usually lower in concentration than malignant bands and not associated with Bence Jones protein. Bence Jones protein is a free monoclonal immunoglobulin light chain in the urine. The level of monoclonal immunoglobulin at initial diagnosis is a prognostic indicator of disease progression.[213] During treatment, the serum concentration of urinary Bence Jones protein may reflect the success of therapy. Lower levels are associated with more favorable outcome. The electrophoretic patterns of serum paraproteins are discussed in Chapter 20.

Bladder Cancer Markers

It is estimated that 600,000 Americans are currently affected by bladder cancer, and almost 54,000 new cases will be reported each year. The symptoms range from intermittent hematuria to voiding problems or dysuria. The most common type of cell seen is transitional cell carcinoma (TCC), and the most frequent symptom is hematuria. Bladder cancer is staged pathologically and treated on the basis of the extent of tumor invasion. Carcinoma in situ (stage Tis) and superficial bladder cancers (stages Ta and T1) occur on the epithelial lining and do not invade the muscle layer. Stage Ta tumors are confined to the mucosa, and stage T1 tumors superficially invade the lamina propria. Stage T2 tumors extend into the muscle layer and T3 tumors invade beyond the muscle layer. Stage T4 tumors have metastasized to local nodes or distant organs.

Urinary Bladder Tumor Markers

Detection of bladder cancer is through either cystoscopy or cytology of shed cells, or by detection of noncellular markers, such as NMP22, complement factor-H (CFH), fibronectin, immunocyt, and bladder tumor associated (BTA) analytes voided in urine.[76,205] Tumor antigens present in urine are the easiest to analyze; however they cannot be used as the sole mechanism for tumor detection. They should be used in a complementary manner with cystoscopy and cytology. NMP22, in a series of 300 patients with hematuria, using a cut-off of 10 U/mL, detected 100% of the bladder cancer cases, with a specificity of 85%.[265] In another study, NMP22 and fibronectin were found to have superior sensitivity to that of cytology; however NMP22 and cytology have the highest specificity.[65] Calreticulin has also been suggested as a marker for bladder cancer and its diagnostic accuracy evaluated.[104]

A fluorescence in situ hybridization (FISH) technique, UroVysion, uses fluorescently labeled probes to detect aneuploidy of chromosomes 3, 7, and 17, and deletion of the 9p21 locus that contains the tumor suppressor p16, which is the most common alteration seen in urothelial carcinoma. Table 23-13 compares cytology with that of UroVysion for the detection of bladder cancer.[190]

Nuclear Matrix Protein (NMP22)

Nuclear matrix proteins (NMPs) make up the internal structure of the nucleus. Their function has been associated with regulating key reactions in the nucleus, such as DNA replication and RNA synthesis. The NMPs released by the cancer cell may be different from the normal cell. Furthermore, different types of cells may have different NMPs. Soluble NMPs could be detected in the sera of cancer patients in higher concentrations than the sera from normal subjects.[165] In a multicenter follow-up study (125 cystoscopies) of 90 patients with 33 pathologically confirmed TCC of the urinary tract, 70% of the 33 recurrences had urinary NMP greater than 10 U/mL. Of the patients with NMP less than 10 U/mL, 86% had no malignancy at subsequent cystoscopy.[215]

An ELISA for the measurement of an NMP called nuclear mitotic apparatus protein in urine sample has been approved by the U.S. FDA for the management of patients with TCC of the urinary tract. The test is called NMP22 and is manufactured by Matritech, Inc. (Newton, Mass.)

Bladder Tumor Associated Analytes

A qualitative test for BTA analytes in urine, termed the BTA stat. test, has been developed. BTA analytes are high molecular weight polypeptides composed of complexes of basement membrane proteins. The presence of BTA analytes in urine is thought to involve either invasion of the basement membrane by tumor, production by the tumor itself, or a combination of these, which may be linked with the body's immune response. If BTA analytes are present in a significant level, they will combine with latex particles to produce an agglutination reaction, which produces a visible color change on the

TABLE 23-13 Comparison of Cytology Sensitivity With UroVysion Sensitivity for the Detection of Bladder Cancer by Stage

	UroVysion (percent)	Cytology (percent)
Stage		
Ta, Grade 1-2	62	23

BTA stat. test strip. A multicenter trial compared the BTA stat. test with voided urine cytology studies in 499 patients undergoing surveillance cystoscopy for recurrent bladder cancer. The BTA stat. test identified 40% of patients with positive cystoscopy results, and cytology detected 17%. A positive test may provide a higher degree of suspicion for recurrence.[189] A quantitative test in ELISA format, BTA TRAK, is also available.

Heat Shock Proteins

Heat shock proteins (HSPs) are a conserved group of proteins that were first identified by their ability to be induced by heat and other stressors. Numerous functions have been associated with HSPs, most notably as chaperones to stabilize cellular proteins during periods of unfavorable conditions. HSPs associate with many cellular components, including signal transduction proteins (kinases and phosphatases), steroid receptors, and components of the apoptotic machinery. The ability of HSPs to interact with various cellular components and protect them from stressors, coupled with the fact that increased expression is seen in a number of tumors, suggests that they may play a role in tumorigenicity. Increased expression of HSP27 is seen in breast cancer, endometrial cancer, and leukemia. HSP70 is increased in breast cancer, endometrial cancer, osteosarcoma, and renal cell tumors. High expression of HSP27 and HSP70 in breast, endometrial, or gastric cancer is correlated with metastasis, poor prognosis, and resistance to chemotherapy.[78] HSP60 and HSP90 are also overexpressed in breast and lung cancers, leukemias, and Hodgkin's disease.

S-100 Proteins

The S-100 proteins are a group of at least 19 related calcium binding proteins. They all contain two high affinity and selective EF-hand calcium binding domains. Their physiological role is uncertain; however some members have been associated with cancer progression, namely S-100A4, S-100A2, S-100A6, and S-100β.[139] S-100A4 is normally expressed in selected immune cells, with faint expression in keratinocytes, melanocytes, and Langerhans' cells. It is not expressed in breast, colon, thyroid, lung, kidney or pancreas. The expression of S-100A4 in breast cancer, esophageal-squamous carcinoma, and gastric cancers correlates with a worse outcome and more aggressive disease, and was shown to be an independent marker of prognosis in multivariate analysis. The lack of expression in normal tissue and its expression in cancer tissue make it an excellent candidate for routine histological use as a cancer marker.

S-100β is routinely used as a diagnostic histological marker of melanoma and melanoma metastases. Recently the measurement of serum levels of S-100β has been investigated for monitoring disease recurrence. In the absence of melanoma, serum S-100β levels are normally undetectable; however with recurrent disease S-100β levels rise. Using an immunoassay (LIA-mat Sangtec 100; Byk-Sangtec Diagnostics, Germany) a cut-off of 0.12 μg/L has been suggested[77] that gives a sensitivity and specificity of 0.29 and 0.93, respectively, with a diagnostic accuracy of 0.84. S-100β is a more sensitive and specific marker for recurrent melanoma and is able to detect recurrence earlier than either LD or alkaline phosphatase (traditional markers of melanoma recurrence).

Autoantibodies

Autoantibodies are antibodies that specifically recognize self-antigens, or proteins. They are normally thought of in the context of autoimmune disease; however autoantibodies have been used for the detection and monitoring of cancer.[59] The event that triggers the development of autoantibodies can either be an infection that through molecular mimicry breaks self-tolerance in a susceptible individual or the inappropriate expression of a self-antigen, such as a cancer antigen. Various cancers produce either proteins or antigens that are recognized by the immune system and are targets for the development of autoantibodies. The detection and monitoring of cancer by the use of circulating tumor markers mainly consist of the detection proteins or antigens that are not normally present in the circulation or when a notable change in the level of these antigens occurs. A number of cancers express new antigens (abnormally glycosylated MUC1, detected by CA 15.3) or overexpress existing antigens, such as HER-2/neu, and autoantibodies that recognize these tumor antigens can also be detected.

Healthy individuals normally either do not have autoantibodies or have them at a very low titer, and a change or rise can signify the development of cancer or another disease state. A number of cancer antigens have been investigated for their ability to induce detectable autoantibodies, including p53, MUC1, c-myc, and c-erbB-2. For example, accumulation of mutant p53 proteins within tumor cells may lead to the development of autoantibodies. Nine percent to 48% of primary breast cancer patients have detectable anti-p53 antibodies, as do 11% to 64% of lung cancer patients.[59] Anti-p53 antibodies have also been detected in hepatocellular, bladder, colorectal, gastric, and other cancers.[7-9]

Many cancers are heterogeneous, and do not consistently express tumor markers. It is clear that no single tumor marker will detect all cancers. Therefore the detection of multiple antigens should increase the sensitivity of detection. This is also the case with autoantibody detection. Using a single autoantibody the detection of primary breast cancer was between 35% and 47%; however using four autoantibodies (p53, MUC1, c-myc, and c-erbB-2) the sensitivity can be increased to 82%.[59]

Autoantibodies are also useful in prognosis and monitoring of disease. Elevated levels of autoantibodies to p53 are associated with a poor prognosis, independent of the tumor-related antigens.[59] This may be due to the fact that expression of the tumor antigen at a distant and/or abnormal site triggers an immune response. The titer of the autoantibodies also tends to follow the amount of tumor antigen, which

can provide information about tumor volume. In addition, the concentration of autoantibodies decreases in relation to the antigen load, but will quickly rise again in recurrent disease because of a secondary immune response when the antigen is re-introduced (recurrent disease). The use of autoantibodies with the greatest potential is for the early detection of cancer, since a small amount of the antigen has the ability to generate a vigorous humoral immune response; however more research is necessary before autoantibodies will be part of the standard tests ordered.

THYROGLOBULIN AND ANTIBODIES

Biochemistry

Thyroglobulin (Tg) is produced by the thyroid gland as the precursor to thyroid hormone (see Chapter 52).

Clinical Applications

The main use of Tg measurement is as a tumor marker for patients with a diagnosis of differentiated thyroid cancer. Approximately two thirds of these patients have an elevated preoperative Tg level. An elevated preoperative level of Tg confirms the tumor's ability to secrete Tg and validates the use of postoperative measurement of Tg to monitor for tumor recurrence. Postoperatively, the most sensitive method to detect residual tumor or metastasis is after TSH stimulation. In well-differentiated tumors, a tenfold increase in Tg levels is seen after TSH stimulation.[217] Poorly differentiated tumors, that do not concentrate iodide, may display a blunted response to TSH stimulation.

Antithyroglobulin antibodies can also be used to monitor residual disease and/or recurrence. Serial anti-Tg measurements may be an independent prognostic indicator of therapy, because an increase in anti-Tg antibodies may suggest recurrence of the tumor.[218]

Analytical Methodology

IMA and RIA are the two main methods used for the measurement of Tg. The IMA assays have the advantage of having a shorter incubation time and are automatable; however, they suffer from greater interferences. The main interferants in both assays are antithyroglobulin antibodies, which cause an underestimation of Tg levels in the IMA. Antithyroglobulin antibodies can either be measured directly in all patients or if both IMA and RIA are used to measure Tg, a discordant result suggests the presence of anti-thyroglobulin antibodies.

CHROMOGRANINS

Chromogranins are a family of proteins that are major components of the secretory granules of most neuroendocrine cells.

Biochemistry

The granin family consists of three members, chromogranin A (CgA), B (CgB), and secretogranin II, III, IV, and V.[67] Chromogranins are found in neuroendocrine cells throughout the body, including the neuronal cells of the central and peripheral nervous systems. Intracellularly located chromogranins have been suggested to play a role in the regulation of secretory granules. In addition, the secreted chromogranins can be proteolytically processed to form bioactive peptides. Chromogranin A has been the most studied of the chromogranins, has been shown to be widely expressed by neuroendocrine tissue, and is co-secreted by neuroendocrine cells along with peptide hormones and neuropeptides. This wide distribution and co-secretion make it an excellent histochemical and plasma marker of neuroendocrine tumors.

Clinical Applications

Both CgA and CgB are useful in detecting various neuroendocrine tumors including carcinoid tumors, pheochromocytoma, and neuroblastoma. In most cases CgA is produced at higher levels than CgB; however in some cases, CgB is positive when CgA is negative, therefore both should be measured where possible. In the case of carcinoid tumors, the foregut and mid-gut tumors are normally functional tumors producing serotonin. CgA is as specific for detection of both foregut and midgut carcinoid tumors as the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA), and is the preferred marker in hindgut tumors, which commonly are non-functional.[59] Although the nonfunctional tumors have lost the ability to secrete serotonin, they retain the ability to secrete chromogranins. For detection of pheochromocytomas, CgA is at least as sensitive and specific as plasma catecholamines or urinary metanephrins.[21]

Analytical Methodology

Currently, CgA is measured by immunoassay. Depending on the assay, polyclonal or monoclonal antibodies are used. Care must be taken in choosing an assay since CgA and the other chromogranins are heavily processed after release, which may render them nondetectable by the assay and produce false-negative results. Therefore an assay that recognizes both the intact and processed molecule may be desirable.

RECEPTORS AND OTHER MARKERS

Other tumor markers—including catecholamines, polyamines, lipid-associated sialic acid, and receptors—have been used clinically with various degrees of success (Table 23-14). Receptors are probably the most successful of this group of markers. The catecholamines and their metabolites are discussed in Chapter 29.

ESTROGEN AND PROGESTERONE RECEPTORS

Estrogen and progesterone receptors are used in breast cancer as indicators for hormonal therapy.[250] Patients with positive estrogen and progesterone receptors tend to respond to hormonal treatment. Those with negative receptors will be treated using other therapies, such as chemotherapy.

TABLE 23-14 Other Tumor Markers

Name	Nature	Type of Cancer
Estrogen and progesterone receptors	(Tissue)	Breast
Catecholamine metabolites	(Urine) VMA, HVA, metanephrines	Neuroblastoma, pheochromocytoma
Hydroxyproline	(Urine)	Bone metastasis (breast), multiple myeloma
Lipid-associated sialic acid	Sialic acid bound to lipid	Gastrointestinal, lung, rheumatoid
Polyamine	(CSF)	Brain
	(Urine)	Various

VMA, Vanillylmandelic acid; *HVA*, homovanillic acid; *CSF*, cerebrospinal fluid.

Hormone receptors also serve as prognostic factors in breast cancer. Patients with positive receptor levels tend to survive longer.

Biochemistry

Estrogen receptors (ER) and progesterone receptors (PR) are members of the nuclear steroid hormone receptor family, and are involved in hormone directed transcriptional activation. The general structure of nuclear steroid hormone receptors, including ER and PR, consists of a large N-terminal domain containing transcriptional activation domains, a DNA-binding domain, a hinge region, and the hormone-binding domain at the C-terminus. Both the ER and PR are present in a large protein complex, and upon hormone binding, some members of the complex dissociate and the receptors bind to their respective response elements, and activate transcription.

Estrogen and progesterone each have at least two separate receptors. Estrogen has ERα and ERβ, which are transcribed from separate genes. ERα and ERβ show 96% and 58% homology in their DNA- and hormone-binding domains, respectively, with a more divergent sequence in the N-terminal region.[118] Two forms of PR, PR-A and PR-B, also exist and are both transcribed from the same gene. PR-A lacks the first 165 amino acids of PR-B.

The ERs and PRs are found in target tissue cells, such as in the uterus, pituitary gland, hypothalamus, and breast, and appear to be involved in tumor development and progression. Furthermore, ER and PR status correlate with both prognosis and treatment response, therefore measuring the levels of ER and PR is clinically useful.

Clinical Applications

Measurement of ER levels in breast tumor tissue is useful as both a prognostic indicator and in determining the probability of hormonal therapy. Of patients with carcinoma of the breast, 60% have tumors that are ER positive. ER-positive tumors are 7 to 8 times more likely to respond to endocrine therapy, such as tamoxifen, toremifene, and droloxifene. Furthermore, the U.S. National Cancer Institute Consensus Statement suggests that all breast cancer patients who have positive ER findings should undergo hormonal treatment regardless of their age, menopausal status, nodal status, or tumor size. Ninety-five percent of the patients with ER-negative tumors fail to respond. The greater the ER content of the tumor, the higher the response rate to endocrine therapy. Approximately one third of women with metastatic breast carcinoma obtain an objective remission following various types of endocrine therapy directed at lowering their estrogen levels. Such therapy includes oophorectomy, hypophysectomy, and adrenalectomy (ablative therapy), and administration of antiestrogens and androgens (additive therapy). As a prognostic indicator, ER positivity suggests a better 5-year outcome; however after 5 years, ER-negative tumors have a better prognosis.[59]

Occasionally, a tumor is defined as ER negative, but the patient responds to endocrine therapy (false-negative results yielded in an ER assay). The following are explanations of false-negative results:

1. Incorrect handling and storage of tissue sample that may degrade the thermolabile receptor proteins. During the collection, the specimen must always be kept cold and transported on ice to its storage in a freezer at −70 °C.
2. Inadvertent biopsy of neighboring nonmalignant tissue.
3. Low protein concentration in the assayed sample.
4. High levels of endogenous estrogens that saturate receptor sites and render them undetectable when standard methodology is used.

False-positive results of ER assays (ER-positive tumor but no response to endocrine therapy) are more common than are false-negative results. The most frequent explanation is heterogeneity of tumor with biopsy of a site that is not representative of the other tumor deposits. In addition to this problem, evidence exists that some tumor cells have receptor defects distal to the initial binding step (e.g., variant cells are able to bind steroid in the cytoplasm but not transport the receptor to the nucleus).

In 1996 ERβ was identified as a second ER; it is thought to modulate the activity of ER (now renamed ERα). When bound to hormone, ERα and ERβ signal differently at the activator protein-1 (AP-1) site: ERα activates transcription, and ERβ represses transcription.[161] This ability may have implications as to which isoform of ER is measured, and may affect its prognostic use. Duffy's group reported that the level

of ERβ expression between breast carcinoma and breast fibroadenoma tissue was greatly decreased in breast carcinoma tissue, and the expression of ERα was not.[59] They also showed that the routinely used ELISA method for quantitation of ER predominantly detects ERα. The fact that ERβ seems to attenuate ERα signaling coupled with the fact that levels of ERβ are inversely proportional to PR and ERα levels suggests a possible mechanism for ER-positive tumors that do not respond to hormonal treatment.[59]

PR assay is a useful adjunct to the assay of ERs. Because PR synthesis appears to be dependent on estrogen action, measurement of PR activity provides confirmation that all the steps of estrogen action are intact. Indeed, metastatic breast cancer patients with both ER- and PR-positive tumors have a response rate of 75% to endocrine therapy, whereas those with ER-positive and PR-negative tumors have a 40% response rate. In addition, only 25% of ER-negative/PR-positive patients respond to endocrine therapy, whereas fewer than 5% of ER-negative/PR-negative patients respond. The percentage of positive specimens is greater in postmenopausal women than in those who are premenopausal.

Analytical Methodology

Titration assays, enzyme immunoassays,[98,102] and immunocytochemical assays[36,150,187] are used to measure steroid hormone receptors.

The classic quantitative biochemical method for assaying steroid receptors in tumor tissue specimens is the *multiple-point dextran-coated charcoal (DCC) titration* assay. However, in comparison with the classic DCC assays, enzyme immunoassays are preferred as they cost less and are simpler, require less time, and can be performed using less tissue than DCC titration assays.

With immunocytochemical assays, monoclonal antibodies are used to detect steroid receptor proteins in frozen tissue sections, paraffin-imbedded tissue, fine-needle aspirates, and malignant effusions using immunocytochemical techniques. These methods are useful in evaluating very small lesions when adequate tissue is not available for performing the conventional DCC method or when tissues have been fixed or imbedded. In these procedures, the primary monoclonal antibody is incubated with a thin section of tissue mounted on a microscope slide. Localization and visualization of receptor material are subsequently accomplished by an indirect immunoperoxidase technique. Specimens having staining in at least 20% of the malignant cells are usually considered receptor positive. Immunocytochemical assays are not influenced by the presence of estrogens, antiestrogens, or steroid-binding proteins. In addition, immunocytochemical methods make it possible to study receptor content specifically in malignant cells.

Androgen Receptor

Androgens, namely testosterone and dihydrotestosterone (DHT), are involved in growth and maintenance of the prostate gland. Testosterone and DHT exert their effect through the androgen receptor (AR), a classical nuclear steroid hormone receptor. The AR activates the transcription of genes containing androgen response elements, and thereby modulates prostate growth and development. The role of the AR in development and progression of prostate cancer is suggested by the fact that antiandrogen therapy is highly but transiently effective, and anti-androgen therapy can stimulate prostate cancer cells, as seen in antiandrogen withdrawal syndrome.

Two polymorphic repeats have been identified, a CAG and a GGN repeat, that correlate with prostate cancer development. Shorter CAG repeats are associated with greater cancer risk and increased prostate cancer aggressiveness. Also, mutations have been found that cause inappropriate activation of the AR by estrogens, progestins, glucocorticoids, and antiandrogens that promote prostate cancer cell growth, suggesting that these mutations play a role in cancer progression and development of resistant tumors.

Hepatocyte Growth Factor Receptor (c-Met)

The hepatocyte growth factor (HGF) receptor, also known as c-Met, is a proto-oncogene tyrosine kinase receptor predominantly expressed on healthy epithelial cells. The natural ligand for c-Met is hepatocyte growth factor/scatter factor (HGF/SF) and upon activation by its ligand induces a wide array of cellular responses, including proliferation, survival, angiogenesis, wound healing, scattering, motility, invasion, and branching morphogenesis. c-Met was originally identified as a fusion gene between the TRP locus and the c-Met locus in a human osteogenic sarcoma cell line treated with a chemical carcinogen. This fusion produced a constitutively active receptor that activates downstream proliferation, survival, and migration pathways.

The involvement of c-Met in the progression of cancer has been investigated in numerous types of tumors. The overexpression of c-Met in prostate, colorectal, breast, malignant melanoma, hepatocellular, and uterine cervix cancer is associated with increased stage, metastatic potential, and a poor prognosis. Increased mRNA copy number of c-Met in colorectal cancer has been correlated with the depth of invasion.[233] In addition, its increased expression in breast cancer tumors correlates with a shortened survival time and is an independent prognostic marker from HER-2, EGFR, and hormone receptor status.[236] Overall, both inappropriate expression and overexpression of c-Met appear to be involved in metastases and invasion and correlate with a worse clinical outcome. Considering the potential role that c-Met plays in cancer progression and metastases, it is being studied as a potential target for drug therapy by various investigators.

Epidermal Growth Factor Receptor

The epidermal growth factor receptor (EGFR) is a prototype of a family of tyrosine kinase receptors. The natural ligands for the EGFR are epidermal growth factor (EGF) and transforming growth factor (TGF)-α. In cancerous tissue, these

growth factors can promote growth both in a paracrine and autocrine fashion. In an analysis of more than 200 studies completed between 1985 and 2000, it was determined that the overexpression of EGFR had prognostic value in a number of cancers.[151] The EGFR was found to be a strong prognostic indicator in head and neck, ovarian, cervical, bladder, and esophageal cancers. Patients with elevated EGFR levels showed reduced overall survival in 70% of studies. In breast, colorectal, gastric, and endometrial cancers, EGFR was found to be a moderate prognostic indicator, with 52% of studies showing reduced survival when elevated levels of EGFR are observed. The fact that EGFR is implicated in the progression of various tumor types, it represents a potential point of intervention and treatment for these cancers. A number of compounds have been developed that inhibit EGFR signaling by blocking ligand binding or inhibition of tyrosine kinase activity.

GENETIC MARKERS

Cancerous growth is an inheritable characteristic of cells and is thought to be the outcome of genetic changes.[214] Multiple genetic alterations may be necessary for the transformation of a cell from a normal state to a cancerous one and, finally, for metastatic spread. Therefore, the evaluation of chromosomal changes may fill the gap left by the traditional serum biochemical markers in establishing cancer risk and screening for cancer (see Chapters 36 and 37).

Two classes of genes are implicated in the development of cancer: oncogenes (cell activation genes—Table 23-14) and suppressor genes (genes involved in the recognition and repair of damaged DNA—Table 23-15).[79,246] *Oncogenes* are derived from proto-oncogenes that may be activated by dominant mutations, such as point mutations, insertions, deletions, translocations, or inversions. Most oncogenes code for proteins that function at some stage of activation of cells for proliferation, and their activation leads to cell division. Most oncogenes are associated with hematological malignancies, such as leukemia and, to a lesser extent, solid tumors. The other class of tumor genes, the *suppressor genes,* has been isolated from mostly solid tumors. The oncogenicity of suppressor genes is derived from the loss of the gene rather than their activation as with oncogenes. Deletion or monosomy may lead to the loss of tumor suppressor genes. The major tumor suppressor gene, p53, functions to repair damaged DNA by apoptosis (programmed cell death). Repair is mediated by activation of the production of p21, which blocks the cell cycle in late G_1 to allow repair to take place.[105] The loss of function of this gene caused by loss or mutation may result in the inability of the DNA repair process and lead to the development of tumorigenesis.

It is expected that the knowledge of the sequence of the Human Genome and the identification of all genes will allow the determination of which genes are differentially or aberrantly expressed in cancer, and the role of mutations or rearrangements of these genes in the development and progression of cancer (see Chapter 39). For example, the identification of single nucleotide polymorphisms and other genetic differences between individuals may allow the development of models for predicting individual predisposition to cancer and the deployment of effective prevention strategies, such as frequent surveillance, chemoprevention, nutritional and lifestyle modification, etc.

ONCOGENES

Proto-oncogenes are normal cellular genes related to tumor virus genes. Activation of proto-oncogenes is found to be associated with cancer. These genes code for products that are involved in normal cellular processes, such as growth factor signaling pathways. Overexpression of the oncogene will lead to abnormal cell growth, resulting in malignancy. Of the more than 40 proto-oncogenes recognized, only a few have been shown to be useful tumor markers[199] (see Table 23-15).

TABLE 23-15 Some Oncogenes Found in Human Tumors

Oncogene	Function	Product	Type of Cancer
N-*ras* mutation	Signal transduction	Guanine diphosphate (GDP)/ guanine triphosphate (GTP) binding protein	Acute myeloid leukemia, neuroblastoma
K-*ras* mutation	Signal transduction	GDP/GTP binding protein	Leukemia, lymphoma
c-*myc* translocation	Transcription regulation	Binds to DNA	B- and T-cell lymphoma, small cell lung carcinoma
c-*erb* B-2 amplification	Growth factor receptor	Tyrosine kinase	Breast, ovarian, gastrointestinal
c-*abl*/*bcr* translocation	Signal transduction	Tyrosine kinase	Chronic myelocytic leukemia
N-*myc* amplification	Transcription regulation	Binds to DNA	Neuroendocrine
bcl-2	Blocks apoptosis	Mitochondrial membrane protein	Leukemia, lymphoma

ras Genes

The *ras* genes were first identified as being responsible for the tumorigenic properties of the Harvey (H-*ras*) and Kirsten (K-*ras*) sarcoma viruses, which produce tumors in animals, and provided the first evidence that cellular counterparts in human cells might be involved in development of human tumors. The proteins coded for by the *ras* genes are located at the inner face of the plasma membrane. They bind to guanine nucleotides and function as molecular switches that regulate mitogenic signals from growth factors to the nucleus via signal transduction pathways.[48] *Ras* proteins are activated in association with protein–tyrosine kinase receptors and are required for growth-factor proliferation or differentiation of a number of cell types.[132] N-*ras* is found on the short arm of human chromosome 1. Changes in N-*ras* appear to be the critical step in carcinogenesis. The mutated N-*ras* gene is found in neuroblastomas and acute myeloid leukemia. Mutated K-*ras* is present in 95% of pancreatic cancers, 40% of colon cancer, and 30% of lung and bladder cancers, and in lower percentages in other tumors.[48] A single point mutation at the twelfth K-*ras* codon changes the coded amino acid from glycine to valine in the p21 protein. This mutation is by far the most frequently found in cancers. K-*ras* mutations appear to correlate with poor prognosis and shorter disease-free survival in patients with adenocarcinoma of the lung and endometrial carcinoma. However, overall, the presence of *ras* mutations has little practical application to determination of prognosis. Activated *ras* is detected by expression of the *ras* gene product, p21, in cancer tissue. By immunohistochemistry, the *ras* product is found not only in about 40% of colon cancers, but also in colon polyps believed to be premalignant. A higher relative intensity of staining for p21-*ras* may discriminate malignant from normal tissues or benign lesions in breast, pancreas, stomach, lung, uterus, or thyroid tissues.[82] The level of expression in tissue appears to correlate with the stage or grade of the tumor, but p21-*ras* may also be seen in some normal tissue, and other studies show no significant difference between benign and malignant tumors. The use of p21 as a tumor marker in tissue or serum is not well established. Mutations of *ras* oncogenes have been detected in the DNA in the stools of 9 of 15 patients with curable colorectal tumors.[204]

c-*myc* Gene

The c-*myc* gene is the proto-oncogene of avian myelocytoma virus. It binds to DNA and is involved in transcription regulation. The gene product, p62, is located in the nucleus of transformed cells, and levels of c-*myc* correlate with the rate of cell division. The c-*myc* protein is essential for DNA replication and enhances mRNA transcription. Activation of the c-*myc* gene is associated with B- and T-cell lymphoma, sarcomas, and endotheliomas.[203] In leukemias and lymphomas, increased c-*myc* expression may be due to amplification or chromosomal translocation of the gene. In acute T-cell leukemias, there is an (8:14) (q24:q11) translocation that results in activation of the gene, and activation of the gene is associated with a poor prognosis. A decrease in expression of c-*myc* after initiation of chemotherapy suggests a favorable response. Overexpression of p62 may be seen in 70% to 100% of primary breast cancers using immunohistochemistry, and the intensity of staining is greater with the increasing stage of the tumor. Amplification in lung carcinomas and gliomas correlates with clinical aggressiveness. There may be a fivefold to fortyfold higher expression of c-*myc* in colon cancers when compared with normal mucosa, but the level of expression does not correlate with progression. A similar relationship has been found for cervical, gastric, liver, and other cancers. Serum levels of c-*myc* have been used to detect recurrence but not to differentiate cancer and benign conditions.

Her-2/*neu*

The HER-2/*neu* gene (also known as c-erbB-2) is named for its association with neural tumors (*neu*).

Biochemistry

The HER-2/*neu* gene is a 185 kDa transmembrane protein expressed on epithelial cells, and belongs to the EGF family of tyrosine kinase receptors. The EGF family includes four members, the EGF receptor (EGFR; also known as ErbB1/HER-1), ErbB2/HER-2/*neu*, Erb3/HER-3, and ErbB4/HER-4. The EGF family of receptors have the same overall structure consisting of an extracellular ligand-binding domain (ECD), a single transmembrane domain, and an intracellular tyrosine kinase domain. The extracellular domain can undergo proteolytic cleavage by metalloproteases, releasing the ECD (known as p105) into the blood, which can be detected. All are involved in cell proliferation, differentiation, and survival. HER-2/*neu* is normally expressed on the epithelia of numerous organs, including lung, bladder, pancreas, breast, and prostate, and has been found to be elevated in cancer cells.

Clinical Applications

Amplification of HER-2/*neu* is found in breast, ovarian, and gastrointestinal tumors. In breast cancer, it appears to be as useful a prognostic indicator of overall survival as tumor size or ER and PR expression, but not as good as the number of lymph nodes involved in metastases.[210] Elevated serum HER-2/*neu* antigen levels have been shown to correlate with decreased response to hormone therapy of breast cancer.[122] Of the three oncogenes—HER-2/*neu*, *ras*, and c-*myc*—HER-2/*neu* has the strongest prognostic value in breast cancer.

Serum levels of p105 are most useful in breast cancer with some use in ovarian cancer patients.[59,133] p105 levels in breast cancer correlate with a worse prognosis and a shorter disease-free state. Elevated HER-2/*neu* levels also correlate with larger tumor size, lymph node positivity, and high grading score. HER-2/*neu* serum levels are not only to be used for prognosis, but may be used to guide treatment. One study of 719 breast cancer patients showed that elevated levels of

HER-2/*neu* in patients with ER-positive cancers showed significantly worse clinical benefit from hormonal therapies.[128] Furthermore, the study showed a trend toward improved outcome with aromatase inhibitors for patients with elevated serum HER-2/*neu*. Serum levels of HER-2/*neu* are also useful in monitoring breast cancer patients because the HER-2/*neu* levels decrease in response to treatment. Herceptin treatment is now administered only to those breast cancer patients who have HER-2/*neu* amplification.

In ovarian cancer, elevated p105 correlates with increased aggressiveness of the tumor, more advanced clinical stage, and poor clinical outcome. HER-2/*neu* is not useful in combination with CA 125 or alone in distinguishing between benign and malignant ovarian tumors, but it may be useful in identifying a subset of high-risk patients.[59]

Analytical Methodology

Immunohistochemistry has been used to detect increased levels of the HER-2/*neu* protein in cancer cells.[59] FISH has been used for detection of HER-2/*neu* gene amplification. Immunohistochemistry is a relatively simple procedure and can be done in most labs, but suffers from interanalyst variation. FISH is less analyst dependent, but only detects increases in gene copy number. Detection of the ECD of HER-2/*neu* (p105) in serum is by ELISA and automated immunoassay. Both assays use the same monoclonal antibodies recognizing different epitopes of the ECD, which does not cross-react with any other member of the EGF family. Importantly, there is no interference from the therapeutic monoclonal antibody, Herceptin, with either assay.[133] The ELISA has a lower detection limit of 3.4 ng/mL and an upper limit of 36 ng/mL, and the automated immunoassay has a linear range from 0.1 to 250 ng/mL. The upper limit of normal for both assays has been set at 15 ng/mL.

bcl-2

The product of the *bcl*-2 oncogene is a novel 239 amino acid, 25 kDa integral membrane protein that localizes primarily to the mitochondrial membranes and to other cellular membranes. This protein is known to inhibit apoptosis (programmed cell death) and contribute to survival of cancer cells, especially lymphoma and leukemic cells.[140] The *bcl*-2 proto-oncogene was identified in follicular lymphomas wherein a 14:18 translocation results in formation of a *bcl*-2-immunoglobulin heavy-chain fusion gene. Activation of the *bcl*-2 gene through the immunoglobulin promoter results in production of high levels of *bcl*-2 protein. The protein is normally expressed on cells that have a long life span (e.g., neurons) and on the proliferative cells in rapidly renewing cell lineages, such as basal epithelial cells. The *bcl*-2 oncogene is highly expressed in a variety of hematological malignancies, including lymphomas, myelomas, and chronic leukemias (malignancies characterized by prolonged cell survival). In the normal colon, *bcl*-2 positive cells are restricted to basal epithelial cells, whereas in dysplastic polyps and carcinomas, many positive cells may be found in parabasal and superficial regions.[208,214] Abnormal expression of the *bcl*-2 gene appears to be an early event in colorectal carcinogenesis. In addition, overexpression of the *bcl*-2 gene is associated with development of resistance to cytotoxic cancer chemotherapy in a variety of tumors, including epithelial tumors and lymphomas. Thus detection of the *bcl*-2-gene product in tumors is an indication of progression. Future studies may determine its usefulness for predicting resistance to chemotherapy.

BCR-ABL

Chronic myelogenous leukemia (CML) is a myeloproliferative disorder resulting from the clonal expansion of a transformed multipotent hematopoietic stem cell. In approximately 90% of CML patients, the transforming event is the formation of the Philadelphia chromosome, a balanced translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)] creating the BCR-ABL fusion gene. The protein derived from this fusion is a constitutively active cytoplasmic tyrosine kinase that activates a number of signaling pathways leading to growth and inhibition of apoptosis.

Detection of the BCR-ABL is useful in diagnosis of CML and in directing treatment, since there are a number of strategies that target either the BCR-ABL gene by antisense oligonucleotides or the BCR-ABL kinase domain by the tyrosine kinase inhibitor STI571. BCR-ABL detection, by RT-PCR, is also useful in monitoring minimal residual disease in patients who have undergone bone marrow transplantation. In the subset of acute lymphoblastic leukemia patients that harbor the Philadelphia chromosome, a positive RT-PCR for the BCR-ABL gene carries a much higher risk of relapse compared with a negative result. In CML patients after bone marrow transplantation, positive RT-PCR results at 6 to 12 months were associated with a twenty-sixfold elevated risk of relapse, and a positive result at 3 months was not predictive of risk.[177] Also, the amount of BCR-ABL transcript per μg of RNA correlated with risk of relapse; less than 1% of patients with a decreasing level of BCR-ABL mRNA or less than 50 transcripts per μg of RNA relapsed, and 72% of patients with greater than 50 transcripts per μg of RNA relapsed.[127]

RET

The RET tyrosine kinase receptor is involved in kidney morphogenesis, maturation of the peripheral nervous system, and differentiation of spermatogonia. The RET receptor exists in a multimeric complex that includes one of four glycosyl-phosphatidylinositol (GPI)-linked co-receptors (GFRα 1, 2, 3, and 4). The complex responds to four ligands: glial-derived neurotrophic factor (GDNF), neurturin (NTN), persephin (PSP), and artemin. Activation of RET appears to be through dimerization and transphosphorylation of the receptor that recruits numerous signaling molecules. RET, like other tyrosine kinase receptors, activates

TABLE 23-16 Tumor Suppressor Genes: Chromosomal Location and Tumor Types

Chromosome Region	Tumor Type	Gene
3p	Kidney	VHL mutation
5q21	Colorectal	APC mutation
9p21	Bladder, glioblastoma, melanoma	p16 (cdkn2) mutation
11p13	Wilms tumor	*WT1* mutation
11p15	Wilms, breast, hepatoblastoma, rhabdomyosarcoma, bladder	Loss of heterozygosity
13q	Breast	*BRCA2*, RB1
13q14	Retinoblastoma, osteosarcoma, small cell lung	RB1 mutation
16q	Breast	P16 E-cadherin mutation
17q	Neurofibromatosis 1, melanoma, breast	*BRCA1* mutation
17p13	Breast, colorectal, lung, liver, renal cell, bladder, sarcomas	p53 mutation
18q21	Colorectal	DCC mutation
22q	Neurofibromatosis 2, meningioma	NF2 mutation

Other genes indicated by loss of heterozygosity include 1p, 8p, 9q, 10q, and others.

downstream growth pathways, and with uncontrolled signaling cancer can result.

Inappropriate activation of RET has been extensively studied in (1) papillary thyroid cancer, (2) multiple endocrine neoplasia type 2 (MEN2), and (3) familial medullary thyroid carcinoma (FMTC). In each the mechanism of activation of RET is through unregulated dimerization and transphosphorylation of the RET receptor.[4] In the case of papillary thyroid cancer a genetic event creates a fusion between the RET tyrosine kinase domain and a dimerization domain that can be donated by a number of genes. In MEN2A and FMTC point mutations of the extracellular domain induce disulfide linkages between receptors, thus inducing dimerization. In MEN2B, a point mutation in the kinase domain appears to alter the substrate specificity of the tyrosine kinase and presumably leads to inappropriate activation of downstream growth pathways.

Tumor Suppressor Genes

Several suppressor genes associated with human cancer are listed in Table 23-16. Historically, evidence for tumor suppressor genes was derived from the study of hybrid cells of normal and malignant cells that behaved normally.[91,223] It was concluded that normal cells contained a gene that suppressed the expression of malignancy.[92] Reversion to malignancy occurred when the cultured cells lost normal chromosomes. The study of suppressor genes may provide a clue as to the development of cancer from normal cell status to benign and cancerous status and to metastasis. The development of colon cancer requires multiple steps that involve several mutations. The loss of a chromosome 5 gene leads to an increase in cell growth. Early adenoma is associated with the loss of methyl groups on the DNA strand. With the *ras* gene mutation and the loss of the DCC gene on chromosome 18, adenoma advances to the late stage. Carcinoma is found with the loss of the p53 gene on chromosome 17. Finally, metastasis occurs with other chromosome losses.[66] The clinical usefulness of detection of mutations in tumor suppressor genes lies not only in the diagnosis and prognosis of cancer, but also in the prediction of susceptibility when the mutation is carried in the germline, such as with the breast cancer genes *BRCA1* and *BRCA2*.

Retinoblastoma Gene

Retinoblastoma (RB) is a rare tumor of children that occurs both in families and sporadically. The work of Knudson on the familial-specific incidence of RB led to the two-hit hypothesis.[114,115] He reasoned that in the inherited form of the tumor, one mutation was present in the germline and all cells of the body, the other mutational event occurring somatically in one of the cells of the developing retina. In the sporadic form, both mutations occur somatically in the same developing retinoblast, a relatively rare event. The two-hit hypothesis has served as a model for other tumor suppressor genes. The RB gene has been localized to chromosome 13q by loss of a chromosomal banding region in peripheral blood lymphocytes of patients with the familial form and by loss of heterozygosity studies in both RBs and some osteosarcomas. However, most tumors do not have gross deletions but point mutations or small insertions and deletions that result in premature truncation of the protein product.[79] The protein product of the RB gene is a nuclear phosphoprotein with a molecular mass of about 105 kDa (p105-RB).[121] This protein binds to a product of a DNA tumor virus, including the E1A protein of murine tumor virus and the E7 protein of human papillomavirus. When p105-RB is hypophosphorylated, it complexes with transcription factors such as E2F and blocks transcription of genes in S-phase cells. E2F dimerizes with a DP protein and regulates the transcription of several genes involved in DNA synthesis. Inactivation or loss of p105-RB deregulates DNA syntheses and increases cellular proliferation. Thus RB is a

tumor suppressor gene, as it suppresses DNA synthesis. Detection of mutations in RB is useful in determining the susceptibility of an individual to development of RB in the familial form, but it is not used as a tumor marker.

p53 Gene

Of particular interest is the p53 gene[106,138] that lies on chromosome 17q. The native or wild type of p53 is believed to control cell division by regulating entry into the S phase.[105] This controlling effect of p53 protein may be lost by deletion of the gene or production of a competing mutant protein. Seventy-five percent to eighty percent of colon carcinomas show deletion in one p53 allele and a point mutation in the other allele; thus, no wild type of p53 protein is expressed in these tumors. Allelic deletion of p53 occurs only rarely in adenomas (10%), suggesting that p53 inactivation may be a relatively late event in colon carcinogenesis. In addition, up to 70% of breast cancers also have deleted p53. Mutations in p53 produce proteins that inactivate the wild type of p53 protein and allow cells to move through the cell cycle and contribute to the autonomous growth of cancer. A number of different mutations of p53 have been found in human cancers.[124] Most point mutations are localized in four regions of the protein (amino acid residues 117-142, 171-181, 134-158, and 270-286); three "hot spots" affect residues 175, 248, and 273.[124] In addition, selective guanine to thymine mutations are found at codon 249 in human hepatocellular carcinomas taken from patients in high-incidence areas of Africa and Asia[160] associated with aflatoxin exposure. Mutations at codons 245 and 258 are found in Li-Fraumeni syndrome, a rare autosomal dominant syndrome characterized by diverse neoplasms at many different sites in the body.[220]

Monoclonal antibodies to mutated p53 proteins have been developed. The wild type of p53 is normally present in very small amounts that are not detected by immunohistochemistry, whereas the mutant protein accumulates to easily detectable levels. Overexpression of the mutant proteins has been detected in up to 70% of primary colorectal cancers. Overexpression of p53 in breast cancers is associated with poor prognosis, but this association is not as strong as the association with c-*erb*B-2.[153] Up to 75% of small cell lung carcinomas appear to overexpress a mutant (missense mutation) protein. Finally, circulating antibodies to mutant p53 proteins have been found in sera from patients with breast and lung cancer and B-cell lymphomas. This antibody response may be useful in this subset of patients for monitoring for relapse.[138]

p21 *(WAF1)*

The wild type of p53 protein activates transcription of a number of genes, including the *WAF1/CIP1* gene. The p21 protein product of the $p21^{WAF1}$ gene binds to and inhibits the cyclin-dependent protein kinases (cdk) that are active in the G_1 phase of the cell cycle. The cell-cycle arrest function of p53 in response to DNA damage is mediated by p21. Monoclonal antibodies to the p21 protein are now available and are being used to determine if expression of p21 in tumors may be clinically useful.

APC

One of the first events in the putative steps of progression of precursor lesions to colon cancer is loss of the adenomatous polyposis coli (APC) gene in premalignant polyps.[66] The APC gene encodes a 300-kDa protein that may be truncated in cancer cells. The normal function of the APC gene product is not known, but it interacts with proteins, such as α- and β-catenin, involved in cell-cell interactions in epithelial cells. This gene is mutated in hereditary colorectal cancer syndromes, polyposis, and nonpolyposis types. In the polyposis types, hundreds and even thousands or more benign tumors (polyps) arise before the development of cancer. In the nonpolyposis types, very few polyps are seen, but the elevated risk of cancer is essentially similar. The APC gene was detected by an interstitial deletion on chromosome 5q in a patient with hundreds of polyps.[123] Greater than 80% of individuals with hereditary colorectal cancer have germline mutations in one of the APC alleles, including gross deletions or localized mutations. The hereditary forms of colorectal cancer are relatively uncommon, but somatic mutations appear to be of great importance in the development of nonhereditary colorectal cancers. More than 70% of colorectal tumors, regardless of size or histology, have a specific mutation in one of the two APC alleles, and mutation may also be found in other types of tumors, including breast, esophageal, and brain tumors. The usefulness of the loss of the APC protein for diagnosis and prognosis is now under study.

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1), or von Recklinghausen disease, is a dominantly inherited syndrome manifested mainly by proliferation of cells from the neural crest resulting in multiple neurofibromas, cafe au lait spots, and Lisch nodules of the iris.[200] Mutations in the *NF1* gene have been found in about 20% of NF1 patients.[243] The *NF1* gene has been localized to the pericentromeric region of chromosome 17q, band 11. It is a large gene coding for a p300 protein, called neurofibromin. This protein has a high degree of similarity to GTPase-activating proteins.[249] Although the exact mechanism of action of the protein is not known, it appears likely that loss or inactivation of neurofibromin function leads to alterations in signal transduction pathways regulated by small *ras*-like G proteins resulting in continuous "on" signals for cell activation. Inactivating mutations of *NF1* have also been found in colorectal cancer, melanoma, and neuroblastoma.

WT1

The Wilms tumor suppressor gene, *WT1*, is located on chromosome 11p13. It codes for a 45-kDa protein that appears to function in transcriptional regulation by suppressing the

expression of growth-inducing genes, such as early growth response, insulin-like growth factor-2, and platelet-derived growth factor A chain genes.[84] Other chromosomal changes in Wilms tumors indicate that mutations of *WT1* may be only one step in the process of carcinogenesis. Thus identification and understanding of one tumor suppressor gene in a given cancer may only provide a part of the information eventually required to understand the carcinogenic process.

nm23

The nm23 gene was found overexpressed in a nonmetastatic murine melanoma cell line but present in low levels in a highly metastatic cell line. The nm23 gene product appears to be elevated in metastatic breast, colon, and prostatic cancer and is now being evaluated as a new marker for metastases.[75]

BRCA1 and *BRCA2*

A subset of breast cancer patients have been shown to have an inherited predisposition to developing breast and ovarian cancer that is inherited as an autosomal dominant trait.[111] Two genetic loci have been identified: *BRCA1* on chromosome 17q and *BRCA2*, which localizes to 13q12-13.[144,251] *BRCA1* encodes for an 1863 amino acid protein that may act as a transcription factor. The ability to detect mutations in *BRCA1* and *BRCA2* in somatic cells permits the identification of individuals in breast cancer families who carry the mutated gene. It is estimated that as many as 1 in 200 women in the United States may have a germline mutation in the *BRCA1* gene. This has created an ethical dilemma for physicians, patients and their families, and insurance companies and health maintenance organizations as it is now possible to predict with reasonable certainty that an individual who carries a mutation in one of these genes will develop breast and/or ovarian cancer. What should be done if an otherwise healthy individual is shown to carry a *BRCA* gene mutation? Carriers of a *BRCA1* gene mutation have an 85% risk of developing breast cancer and a 45% risk of developing ovarian cancer by the age of 85.[74] Should such patients have preventive mastectomy or ovariectomy? Should insurance companies and health care maintenance organizations have higher rates for carriers? It has always been a goal of cancer research to be able to identify individuals at risk. Now that this is possible, we must develop a policy of how to deal with the information (e.g., see Harper[91] or Petty and Killeen[174]). Although detection of the mutation is not useful as a tumor marker per se, with further understanding of how the mutated gene products act, it may be possible to understand the molecular events for development of some breast and ovarian cancers.

Deleted in Colorectal Carcinoma

The deleted in colorectal carcinoma (DCC) gene encodes for a membrane protein of the immunoglobulin superfamily. The exact function of DCC has yet to be elucidated. However, studies have suggested a role in axonal development as a component of the Netrin-1 receptor, and others have suggested a role in promoting apoptosis.[81] In colon cancer, DCC is thought to act as a tumor suppressor, thus, deletion or reduced expression correlates with increasing stage and a poorer prognosis.[154] Conversely, loss of DCC expression in gastric cancer was associated with a better prognosis and higher tumor cell differentiation.[154] More work is necessary to determine the exact role of DCC in both colon cancer and other gastric cancers.

PTEN

The PTEN tumor suppressor gene is mutated in numerous cancers, and is probably underestimated in its importance in tumor formation and progression.[231] PTEN functions as a phosphatase that negatively regulates phosphoinositide 3-kinase (PI 3-K) signaling by dephosphorylating the D3 position of phosphatidylinositol (3,4,5)-triphosphate [PtdIns(3,4,5)P_3]. PI 3-kinase and its product PtdIns(3,4,5)P_3 are involved in activation of signaling pathways leading to inhibition of apoptosis, cell migration, cell size, and chemotaxis. Mutation or inactivation of PTEN allows uncontrolled activation of the downstream pathways, which contribute to tumorigenesis.

Germline mutations in PTEN cause the (1) Cowden, (2) Lhermitte-Duclos, (3) Bannayan-Zonana, and (4) Proteus autosomal-dominant syndromes that are all characterized by development of hamartomas and an increased likelihood of tumor development along with other growth-related symptoms. In general, PTEN mutation and/or loss of expression is associated with a more advanced stage, and is a poor prognostic indicator in various cancers, including breast, hepatocellular, endometrial, and cervical.

Single Nucleotide Polymorphisms

Two of the goals of the Human Genome Project are to identify all the approximate 30,000 genes in human DNA and determine the sequences of the 3 billion chemical base pairs that make up human DNA. A by-product of the sequencing effort was the identification of a very large number of single nucleotide polymorphisms (SNPs, single nucleotides that differ between individuals, and these differences are inherited). It has been estimated that one SNP can be found every approximately 1000 bases of genomic sequence. Most of these SNPs are present in introns and only a relatively small number (approximately 60,000 out of the 2,000,000 SNPs) are within exons. It was also identified that groups of SNPs (called haplotypes) are inherited together in a block. It has been hypothesized that it may be possible to correlate SNP composition (e.g., various haplotypes) with disease predisposition. Until now, very few SNPs or haplotypes have been associated consistently with human cancers. Many scientists are currently investigating SNPs and are attempting to correlate them with various diseases. Large numbers of SNPs can now be identified by using either microarrays or mass spectroscopy. The hope is to identify characteristic SNPs or haplotypes that can be used for diagnostic purposes or for

determining future risk (predisposition) for developing certain diseases.

MISCELLANEOUS MARKERS

Markers of Angiogenesis

Angiogenesis, the formation of blood vessels, is a highly regulated and ordered process; however in tumor tissue, this process is rather disordered. The development of tumors is thought to involve the inactivation of tumor suppressor genes and/or the uncontrolled activation of oncogenes. Subsequently, another step in the progression toward malignancy has been identified and has been referred to as the "angiogenic switch."[19,32] The first phase of tumor development is an avascular phase, with a lesion size of 1 to 2 mm. At this point the tumor is in a vascular steady state. The vascular state occurs next where there is rapid and unregulated angiogenesis. The architecture of the newly developing vasculature is very distinct from that of normal vasculature. It is irregularly shaped, dilated and can have dead ends, with irregular blood flow patterns, that makes tumors relatively easy to identify histologically. In normal tissue, there is a balance between proangiogenic signals (VEGF, FGF, PDGFB, EGF, Ets-1, and LPA) and antiangiogenic signals (thrombospondin-1, angiostatin, endostatin, canstatin, and tumstatin). It is believed that in tumors there is an increase in proangiogenic signals. Therefore the measurement of proangiogenic markers may provide prognostic information related to tumor status.

Increases in blood vascular endothelial growth factor (VEGF) and soluble Tie-2 receptor (sTie2) both correlate with the development of metastases, with VEGF being the most powerful predictor of outcome.[45] Ets-1, a transcription factor that activates a number of angiogenic genes, also may serve as a prognostic indicator of uterine cervical cancers. Thrombospondin-1 (TSP-1), an antiangiogenic marker, has been found to be a positive prognostic marker in ductal carcinoma of the breast. Other markers of angiogenesis are being considered as prognostic markers in cancer have been reviewed.[19]

Cell-Free Nucleic Acids

Circulating DNA and RNA has been recognized since the 1970s, but it was not until the late 1980s that the neoplastic characteristics of the DNA were recognized.[103] Circulating DNA and RNA have been proposed as a marker for certain types of cancer. To use circulating DNA as a cancer marker, there must be a mechanism to differentiate normal DNA from neoplastic DNA. This is achieved by detecting mutations in the circulating DNA that are present in the cancer cells (e.g., *ras* mutations that occur in various cancers), by microsatellite analysis of the circulating DNA, or by detection of common cancer-causing chromosomal translocations. Epigenetic alterations of circulating DNA, such as altered methylation patterns, can also be detected. Although this technology is relatively new, over the next decade detection of circulating DNA will join a growing number of clinically useful markers; however a number of questions must still be answered, such as the source of cell-free DNA, and what forms of the DNA and RNA exist. In the future this technology may have the ability to provide a more global picture of the abnormalities present in the patient.

Circulating Cancer Cells

Circulating cancer cells may indicate the presence of cancer (for diagnostic purposes) or cancer dissemination (for prognosis and monitoring therapy). It is generally very difficult to detect rare cancer cells in the circulation. However, the advent of the PCR and the identification of genes that are specifically expressed in certain tissue (normal and cancerous) have allowed for the highly sensitive detection of cancer cells in the circulation.[148,149] Others have used flow-cytometric technology with magnetic separation of cancer cells to achieve the same goal.[235]

Currently, this technology is still under evaluation. However, it is well established that patients with more advanced cancer are more frequently positive for circulating cancer cells and the amount of cancer cells has prognostic significance. PSA and prostate-specific membrane antigen have been used successfully for detection of prostatic cancer cells in the circulation. Zehentner et al. used mammoglobin and other related genes for breast cancer.[259] Despite many limitations of this technology (mainly sample preparation variability and quantification), it may be feasible in the future to identify very rare cancer cells in the circulation for the purpose of diagnosis, prognosis, and monitoring of therapy.[258]

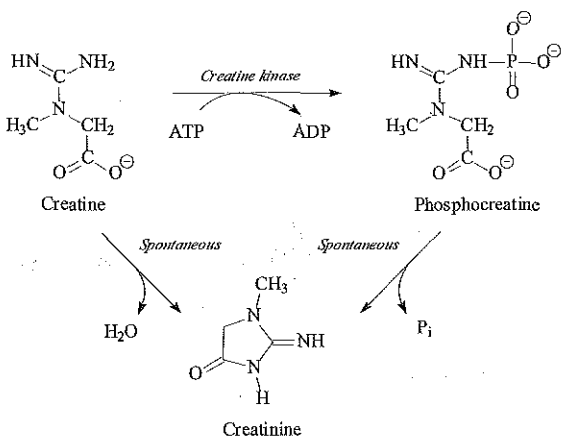
CHAPTER 24

Kidney Function Tests

Edmund Lamb, Ph.D., David J. Newman, Ph.D., and Christopher P. Price, Ph.D.

Quantitation of overall function of the kidneys is based on the assumption that all functioning nephrons are performing normally and that a decline in renal function is due to loss of functioning nephrons quantitatively related to the loss. Thus in nearly all types of diffuse renal disease, impaired function of the kidneys is attributed to a diminished number of functioning nephrons rather than to compromised function of individual nephrons. Because glomerular filtration is the initiating phase of all nephron functions, quantitative or qualitative assessment of filtration—or some variable that bears a constant relationship to it—generally provides the most useful indices for physicians to assess the severity and progress of kidney damage.

Specific defects in particular functions of the nephrons can also be identified and evaluated. For example, assessment of the maximum concentrating capacity of the kidneys gives an estimate of antidiuretic hormone (ADH)–controlled reabsorption of solute-free water in the distal portion of the tubule. Pinpoint defects, caused by genetically determined deficiencies of specific tubular transport systems or ion channels and giving rise to characteristic biochemical disorders, are considered in Chapter 45.



This chapter will describe chemical tests that have proved the most practical and useful for screening for and diagnosing impaired kidney function and for monitoring the course and management of progressive chronic kidney disease (CKD). In general, either plasma or serum is used for most of these tests: the term plasma is mainly used throughout this chapter. This chapter provides an overview of contemporary methodology with reference intervals, the clinical utility of the tests, and the changes that are observed in disease.

CREATININE

Creatinine is the cyclic anhydride of creatine that is produced as the final product of decomposition of phosphocreatine. It is excreted in the urine; measurements of excretion rates are used as diagnostic indicators of kidney function.

BIOCHEMISTRY AND PHYSIOLOGY

Creatine is synthesized in the kidneys, liver, and pancreas by two enzymatically mediated reactions. In the first, transamidation of arginine and glycine forms guanidinoacetic acid; in the second, methylation of guanidinoacetic acid occurs with S-adenosylmethionine as the methyl donor. Creatine is then transported in blood to other organs, such as muscle and brain, where it is phosphorylated to phosphocreatine, a high-energy compound.

Interconversion of phosphocreatine and creatine is a particular feature of the metabolic processes of muscle contraction. A proportion of the free creatine in muscle (thought to be between 1% and 2%/day) spontaneously and irreversibly converts to its anhydride waste product, creatinine. Thus the amount of creatinine produced each day is fairly constant and is related to the muscle mass (and body weight). In

health, the concentration of creatinine in the bloodstream is also fairly constant, although diet may influence the value, depending on the individual's meat intake.[97] Creatinine (MW 113 Da) is present in all body fluids and secretions and is freely filtered by the glomerulus. Although it is not reabsorbed to any great extent by the renal tubules, there is a small but significant tubular secretion. Creatinine production also decreases as the circulating level of creatinine increases; several mechanisms for this have been proposed, including feedback inhibition of production of creatine, reconversion of creatinine to creatine, and conversion to other metabolites.[25,79,88]

Clinical Significance

The clinical utility of creatinine measurement is discussed later in this chapter.

Analytical Methodology

Plasma creatinine is measured as a test of kidney function; both chemical and enzymatic methods are used to measure it.[45,164,205] Most laboratories use adaptations of the same assay for measurements in both plasma and urine.

Chemical Methods: the Jaffe Reaction

Most chemical methods for measuring creatinine are primarily based on the reaction with alkaline picrate. In this reaction, first described by Jaffe in 1886, creatinine reacts with picrate ion in an alkaline medium to yield an orange-red complex. Despite considerable literature on the subject, the reaction mechanism and the structure of the product remain unclear.[228]

The Jaffe reaction is not specific for creatinine. Many compounds have been reported to produce a Jaffelike chromogen, including protein,[35] glucose, ascorbic acid, ketone bodies,[232] pyruvate, guanidine, blood-substitute products,[3] and cephalosporins[213] and the reader is referred to several comprehensive reviews.[28,205] The degree of interference from these compounds is dependent on the specific reaction conditions chosen. The effect of ketones and ketoacids is probably of the greatest significance clinically, although the effect is very method dependent. Thus reports on acetoacetate interference vary from a negligible increase to an increase of 3.5 mg/dL (310 µmol/L) in the apparent creatinine concentration at an acetoacetate concentration of 8 mmol/L. Bilirubin is a negative interferant with the Jaffe reaction. The addition of buffering ions, such as borate and phosphate, together with surfactant, has been used to minimize the effects of this interference. A popular technique in this context has been the addition of ferricyanide ("O'Leary method"), which oxidizes bilirubin to biliverdin, hence reducing its interference.[115,154] Noncreatinine chromogens do not generally contribute to measured urinary creatinine concentration.

Several approaches have been used in an attempt to improve the general specificity of the Jaffe reaction. These have included absorption, and subsequent elution, of creatinine into hydrated aluminum silicate (Fuller's earth, Lloyd's reagent), acid blanking, the use of ion-exchange resins[233] or solvent extraction, and oxidation of interferants with compounds such as cerium sulfate; generally these modifications have not proved practical.

The greatest success in terms of common usage and specificity has come from the use of a kinetic measurement approach in combination with careful choice of reactant concentrations. Although manual methods have traditionally been equilibrium methods, with 10 to 15 minutes allowed for color development at room temperature, kinetic assays were developed in a quest both for specificity and for faster and automated analyses. Early studies of interferences in the kinetic methods identified two kinds of noncreatinine chromogens, those whose rates of adduct formation were very rapid in the first 20 seconds after mixing reagent and sample (e.g., acetoacetate) and those whose rates did not become rapid until 80 to 100 s after mixing (e.g., protein). The "window" between 20 and 80 s therefore was a period in which the rate signal being observed could be attributed predominantly to the creatinine-picrate reaction (some investigators found 60 s as the upper limit of this window). Thus improvement of specificity in the kinetic assays was achieved by selecting times for rate measurements 20 to 80 s after initiation of the reaction (mixing). This approach has been implemented on various automated instruments, and kinetic assays are now the most widely used approach to creatinine measurement. An extensive literature exists on the choice of reactant concentrations and reading interval and on the choice of wavelength and reaction temperature. Brief comments include:

Picrate concentration. The Jaffe reaction is pseudo first order with respect to picrate up to 30 mmol/L, with the majority of methods employing a concentration between 3 and 16 mmol/L. At concentrations above 6 mmol/L, the rate of color development becomes nonlinear, so a two-point fixed interval rather than a multiple-data-point approach is required.

Hydroxide concentration. The initial rate of reaction is pseudo first order with respect to hydroxide concentrations above 0.5 mmol/L; however, at 500 mmol/L there is an increased degradation of the Jaffe complex. Furthermore, at hydroxide concentrations above 200 mmol/L, the blank absorbance increases significantly.

Wavelength. Although the absorbance maximum of the Jaffe reaction is between 490 and 500 nm, improved method linearity and reduced blank values have been reported at other wavelengths, the choice varying with hydroxide concentration.

Temperature. The rate of Jaffe complex formation and the absorptivity of the complex are temperature dependent, measurable differences being observed even between 25 °C and 37 °C. Consequently, temperature control is an important component of assay reproducibility.

Other chemical approaches to the measurement of creatinine have been tried. These include (1) reaction with

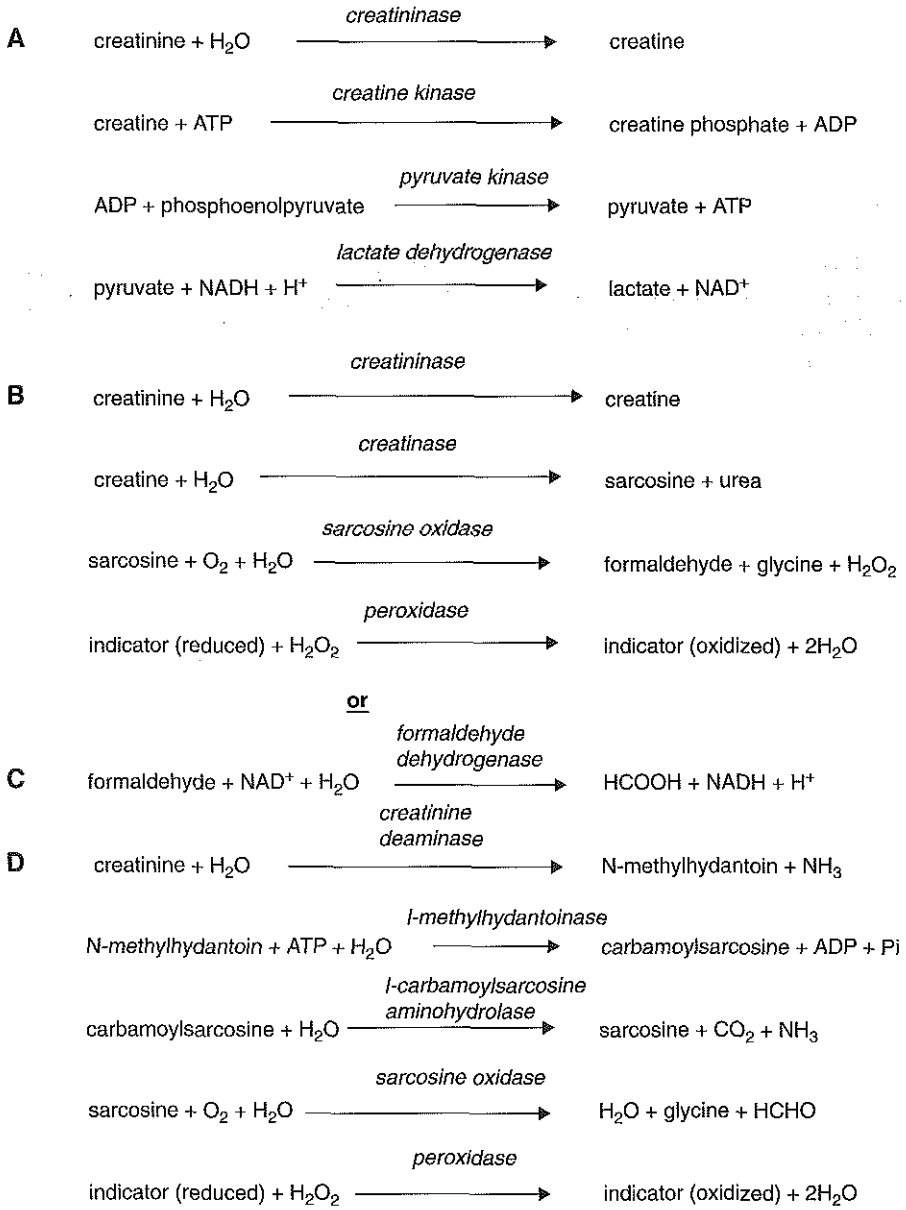


Figure 24-1 Determination of creatinine using a variety of enzymatic methods. For further details, see text.

1,4-naphthoquinone-2-sulfonate; (2) use of *o*-nitrobenzaldehyde to convert creatinine to methylguanidine and its reaction with α-naphthol and sodium hypochlorite under alkaline conditions,[226] and (3) reaction with 3,5-dinitrobenzoic acid.[158] None of these reactions are widely used in clinical laboratories.

Enzymatic Methods

Enzymes from a number of metabolic pathways have been investigated for the enzymatic measurement of creatinine. All of the methods involve a multistep approach leading to a photometric equilibrium (Figure 24-1). There are primarily three approaches, described below.[69,70,216,229]

Creatininase

The enzyme creatininase (EC 3.5.2.10; creatinine amidohydrolase) catalyzes the conversion of creatinine to creatine. The creatine is then detected with a series of enzyme-mediated reactions involving creatine kinase, pyruvate kinase, and lactate dehydrogenase, with monitoring of the decrease in absorbance at 340 nm (Figure 24-1, *A*). Initiating the reaction with creatininase allows for the removal of endogenous creatine and pyruvate in a preincubation reaction. The kinetics of the reaction are poor, and a 30-minute incubation is required to allow the reaction to reach equilibrium. This shortcoming can be overcome by a kinetic approach but with a further reduction in sensitivity. The approach has not been

popular, partly because of poor sensitivity, poor precision, and the relatively high cost of reagents.[229]

Creatininase and Creatinase

An alternative, more popular, approach has used the enzyme creatinase (EC 3.5.3.3; creatine amidinohydrolase), which yields sarcosine and urea, the former being measured with further enzyme-mediated steps using sarcosine oxidase (EC 1.5.3.1; yielding glycine, formaldehyde, and hydrogen peroxide) and peroxidase (Figure 24-1, *B*).[69] The hydrogen peroxide has been detected with a variety of methods. Care must be taken to watch for interference (e.g., by bilirubin) in the final reaction sequence. This problem has been approached with the addition of potassium ferricyanide (with limited success) or bilirubin oxidase. The potential interference caused by ascorbic acid can be overcome by the inclusion of ascorbate oxidase. The influence of endogenous intermediate creatine and urea can be overcome by a preincubation step, initiating the reaction with creatininase. This system has been incorporated in a point-of-care testing device using polarographic detection.[184] An alternative detection system involves measurement of the reduction of nicotinamide adenine dinucleotide (NAD) by formaldehyde in the presence of formaldehyde dehydrogenase (Figure 24-1, *C*).[210]

Creatinine Deaminase

Creatinine deaminase (EC 3.5.4.21; creatinine iminohydrolase) catalyzes the conversion of creatinine to N-methylhydantoin and ammonia.[216] Early methods concentrated on the detection of ammonia using either glutamate dehydrogenase or the Berthelot reaction.[134] An alternative approach involves the enzyme N-methylhydantoin amidohydrolase (Figure 24-1, *D*).[70]

Dry Chemistry Systems

A number of multilayer dry reagent methods have been described for the measurement of creatinine using enzyme-mediated reactions. An early "two-slide" approach employed creatinine deaminase, with the ammonia diffusing through a semipermeable and optically opaque layer to react with bromophenol blue to give an increase in absorbance at 600 nm. A second multilayer film lacking the enzyme was used to quantitate endogenous ammonia, enabling blank correction.[212] A later single-slide method used the creatininase-creatinase reaction sequence[136]: lidocaine metabolites have been reported to interfere with this method.[197] The creatinine deaminase system described above has also been used and adapted for use as a point-of-care testing device (Figure 24-1, *D*).[83] In all cases, the color produced in the film is quantitated by reflectance.

A dry chemistry system has also been described in which a nonenzymatic approach was used, based on the reaction with 3,5-dinitrobenzoic acid.[207]

Other Methods

A definitive method employing isotope-dilution mass spectrometry (MS) has been described.[235] A candidate reference method for creatinine linked to this definitive method uses isocratic ion-exchange high-performance liquid chromatography (HPLC) with ultraviolet (UV) detection at 234 nm.[4] A reagent-free midinfrared method for urinary creatinine measurement has been described.[198]

Quality Issues with Creatinine Methods

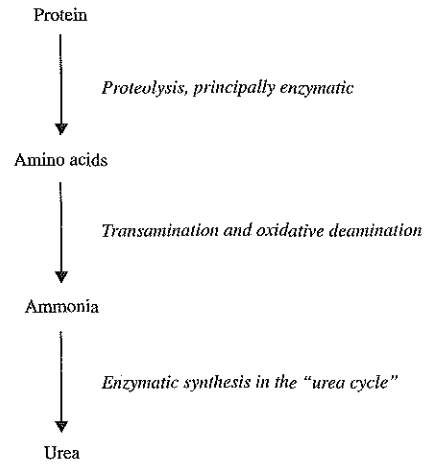
Different methods for assaying plasma creatinine have varying degrees of accuracy and imprecision. With the advent of automated kinetic analysis, within-laboratory, between-day imprecision of approximately 3.0% can be expected at pathological concentrations, with slightly inferior performance within the reference interval.[22] This is still outside desirable performance standards defined in terms of biological variation.[205] Additionally, accuracy remains a major issue. Reference intervals for creatinine clearance and clearance calculated from one of several formulas (see below) will clearly vary depending on the accuracy of the creatinine measurement used in their calculation. The more a method overestimates "true" creatinine, the greater will be the underestimation of the glomerular filtration rate (GFR), and vice versa. As a result of reaction with noncreatinine chromogens, end-point Jaffe methods were typically judged to overestimate true plasma creatinine concentration by approximately 20% at physiological concentrations. Consequently, kinetic, enzymatic, and chromatographic methods can produce creatinine measurements approximately 20% lower than early Jaffe methods. However, since this could result in a relative overestimation of GFR (for example when measuring or calculating clearance), many reagent and instrument manufacturers have calibrated their assays to produce higher plasma creatinine results. As a consequence, many commercially available creatinine methods continue to demonstrate an approximately 20% positive bias compared with HPLC or isotope-dilution MS methods, particularly at concentrations within the reference intervals.[21,35,124] This calibration is not standardized, leading to variation between laboratories. Indeed, a College of American Pathologists survey reports that systematic differences in the calibration of plasma creatinine assays account for 85% of the observed differences between laboratories.[182] Proficiency studies demonstrate that although between-laboratory coefficients of variation (CVs) of <3% are achievable within method groups, overall between-laboratory agreement across methods is much poorer.[35,124] Systematic variation between laboratories of 0.2 to 0.4 mg/dL (18 to 36 μmol/L) is common.[92,124,146] Further, interlaboratory and within-laboratory agreement deteriorates as plasma creatinine concentration nears the reference interval: the exponential relationship between plasma creatinine and GFR means that imprecision at lower creatinine concentrations contributes to greater error in GFR estimation than at higher creatinine concentrations.

Clearly, standardization of creatinine measurement is crucial to the ability to accurately diagnose, stage, and manage CKD. Further, it is a prerequisite to the meaningful

interpretation of epidemiological studies to facilitate healthcare planning.[92] Not surprisingly, there have been calls for the use of an international standard to be used when calibrating plasma creatinine assays.[146] Although undoubtedly desirable, there remain practical barriers to implementation. Matrix problems have been identified when lyophilized preparations with isotope-dilution MS-authenticated creatinine concentrations have been used.[35,124] It is clear that serum- or protein-based human material must be used to calibrate creatinine assays, particularly Jaffe-based ones, but this introduces its own inherent problems, such as differing reactivities of the noncreatinine chromogens in the different Jaffe variations. Further, realignment with an authenticated standard will produce results significantly lower than those to which clinicians are accustomed. This will impact not only on the plasma reference interval, but also on the results of calculated and measured clearance estimates, which will therefore require their own realignment.

Reference Intervals

In summary, the methodology for the measurement of creatinine is complex by virtue of the number of variants of the Jaffe reaction and the innovations attempted using enzymatic procedures to overcome the limitations of the former. Although the enzymatic methods are more expensive, they are used in dry chemistry systems (with their lower reagent requirement) including some point-of-care testing devices. Kinetic Jaffe approaches predominate in wet chemistry analytical systems. Any laboratorian assessing a new creatinine method (e.g., as part of an analyzer purchase) should review the data for that method on interference caused by bilirubin, protein, glucose, and ketones and/or ketoacids. Bilirubin will also be particularly important in enzymatic procedures that generate hydrogen peroxide. Despite criticism of the Jaffe methods, there is invariably a good correlation between them and enzymatic procedures, with the differences likely to be due as much to calibration as to interference.



Given the discussion above, reference intervals for plasma creatinine are clearly method dependent.* Typically, reference intervals for plasma creatinine, measured by Jaffe methods, are 0.9 to 1.3 mg/dL (80 to 115 μmol/L) in men and 0.6 to 1.1 mg/dL (53 to 97 μmol/L) in women.[222] Plasma creatinine concentration in patients with untreated end-stage renal disease (ESRD) may exceed 11 mg/dL (1000 μmol/L). Reference intervals for plasma creatinine are also listed in Chapter 56.

Urinary creatinine excretion is higher in men (14 to 26 mg/kg/day, 124 to 230 μmol/kg/day) than in women (11 to 20 mg/kg/day, 97 to 177 μmol/kg/day). Creatinine excretion decreases with age; typically, for a 70-kg man, creatinine excretion will decline from approximately 1640 to 1030 mg/day (14.5 to 9.1 mmol/day) with advancing age from 30 to 80 years.[164] Measurement of urinary creatinine excretion can be a useful indication of the completeness of a timed urine collection.

UREA

Catabolism of proteins and nucleic acids results in the formation of urea and ammonia—the so-called nonprotein nitrogenous compounds.

Biochemistry and Physiology

Urea ($CO[NH_2]_2$) is the major nitrogen-containing metabolic product of protein catabolism in humans, accounting for more than 75% of the nonprotein nitrogen eventually excreted. The biosynthesis of urea from amino nitrogen-derived ammonia is carried out exclusively by hepatic enzymes of the urea cycle. During the process of protein catabolism, amino acid nitrogen is converted to urea in the liver by the action of the so-called urea cycle enzymes (Figure 24-2).

More than 90% of urea is excreted through the kidneys, with losses through the gastrointestinal tract and skin accounting for most of the remaining minor fraction. Consequently, kidney disease is associated with accumulation of urea in blood. An increase in plasma urea concentration characterizes the uremic (azotemic) state. Urea is neither actively reabsorbed nor secreted by the tubules but is filtered freely by the glomeruli. In a normal kidney, 40% to 70% of the highly diffusible urea moves passively out of the renal tubule and into the interstitium, ultimately to reenter plasma. The back diffusion of urea is also dependent on urine flow rate, with less entering the interstitium in high-flow states (e.g., pregnancy) and vice versa. Consequently, urea clearance generally underestimates GFR. In stage 5 CKD, the osmotic diuresis in the remaining functional nephrons limits the back diffusion of urea so that urea clearance approaches inulin clearance. Measurement of blood and plasma urea has been used for many years as an indicator of kidney function. However, it is generally accepted that creatinine measurement provides better information in this respect. Plasma and urinary urea measurement may still provide useful clinical information in particular circum-

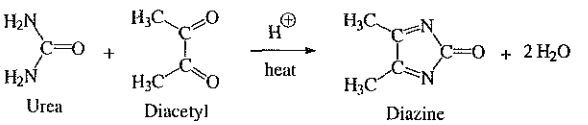
stances, and the measurement of urea in dialysis fluids is widely used in assessing the adequacy of renal replacement therapy (see Chapter 45).

Clinical Significance

A number of extrarenal factors influence the circulating urea concentration, limiting its value as a test of kidney function. For example, plasma urea concentration is increased by a high-protein diet, increased protein catabolism, reabsorption of blood proteins after gastrointestinal hemorrhage, treatment with cortisol or its synthetic analogues, dehydration, and with decreased perfusion of the kidneys (e.g., heart failure). In the above prerenal situations, the plasma creatinine concentration may be normal. In obstructive postrenal conditions (e.g., malignancy, nephrolithiasis, and prostatism), both plasma creatinine and urea concentrations will be increased, although in these situations there is often a greater increase in plasma urea than creatinine because of the increased back diffusion. These considerations give rise to the principal clinical utility of plasma urea, which lies in its measurement in conjunction with that of plasma creatinine and subsequent calculation of the urea nitrogen/creatinine ratio. This can be used as a crude discriminator between prerenal and postrenal azotemia. For a normal individual on a normal diet, the reference interval for the ratio is between 12 and 20 mg urea/mg creatinine (49 and 81 mol urea/mol creatinine). Significantly lower ratios usually denote acute tubular necrosis, low protein intake, starvation, or severe liver disease (decreased urea synthesis). Increased plasma urea with *normal* creatinine concentrations giving rise to high ratios may be seen with any of the prerenal states described above. High ratios associated with *elevated* creatinine concentrations may denote either postrenal obstruction or prerenal azotemia superimposed on kidney disease.

Urea clearance is a poor indicator of GFR, as its production rate is dependent on several nonrenal factors, including diet and the activity of the urea cycle enzymes. A high-protein diet causes significant increases in urinary urea excretion. In addition, the variable amount of back diffusion will influence both plasma and urinary urea concentration.[110] The measurement of urinary urea has little place in clinical diagnosis and management; however, it does provide a crude index of overall nitrogen balance and may be used as a guide to replacement in patients receiving parenteral nutrition. On an average protein diet, urinary excretion expressed as urea nitrogen is 12 to 20 g/day.



Although *blood urea nitrogen* (BUN) continues to be used for ordering the plasma urea nitrogen test, this terminology is incorrect and obsolete, because blood is rarely analyzed for urea. The long-established habit of reporting and expressing results of a urea assay in units of urea nitrogen appears to be strongly entrenched in the United States, although the SI system recommends use of urea, expressed in mmol/L. Thus it behooves students of clinical chemistry to have in mind the conversion factors for urea to urea nitrogen. Because 60 g (1 g molecular weight) of urea contains 28 g (2 g atomic weight) of nitrogen, the factor is 0.467 for converting urea mass units to those of urea nitrogen, and 2.14 for converting urea nitrogen mass units to those of urea. The factor for converting urea nitrogen in mg/dL to urea in mmol/L is 0.357.

Analytical Methodology

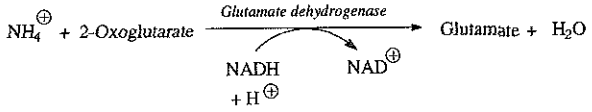
Chemical and enzymatic methods are the two principal approaches that have been used to quantify urea in body fluids.

Chemical Methods

Most chemical methods for urea are based on the Fearon reaction in which diacetyl condenses with urea to form the chromogen diazine, which absorbs strongly at 540 nm.

Because diacetyl is unstable, it is usually generated in the reaction system from diacetyl monoxime and acid. Although once widely used, the method has largely been superseded by enzymatic approaches. For a more detailed description of

direct urea measurement, the reader is referred to a review by Taylor and Vadgama.[217]



Enzymatic Methods

Enzymatic methods for the measurement of urea are based on preliminary hydrolysis of urea with urease (urea amidohydrolase, EC 3.5.1.5; main source jack bean meal) to generate ammonium ion, which is then quantified. This approach has been used in end-point, kinetic, conductimetric, and dry chemistry systems.[217]

Urea

Spectrophotometric approaches to ammonium quantitation include the *Berthelot reaction* and the *enzymatic assay* with glutamate dehydrogenase [L-glutamate:NAD(P) oxidoreductase (deaminating), EC 1.4.1.3].[188] This latter approach has been accepted as a reference method[189] and adapted to a range of analytical platforms.

For plasma assays, the reaction system is usually formulated with urease so that the addition of sample containing urea starts the reaction. A decrease in absorbance resulting from the glutamate dehydrogenase reaction is monitored at 340 nm. In another example of a coupled-enzyme assay system for urea, ammonia produced from urea by urease then reacts with glutamate and adenosine triphosphate (ATP) in the presence of glutamine synthetase (EC 6.3.1.2). Adenosine diphosphate (ADP) produced in this second enzymatic reaction is then quantitated in a third and fourth step using pyruvate kinase (EC 2.7.1.40) and pyruvate oxidase (EC 1.2.3.3), respectively, thus generating peroxide. In the final step, peroxide reacts with phenol and 4-aminophenazone, catalyzed by peroxidase (EC 1.11.1.7), to yield a quinone-monoamine dye that can be quantitated spectrophotometrically.[127]

Methods for the measurement of urea using dry chemistry systems have been described using the urease approach and a range of detection methods.[170,204] Urea has also been measured using a conductimetric method in which a sample and a urease-containing reagent are incubated in a conductivity cell with the rate of change of the conductivity being monitored as the urea is converted to an ionic species. In a potentiometric approach an ammonium ion-selective electrode is employed and the urease is immobilized on a membrane.[183] This principle has been applied in the NOVA 12 (NOVA Biomedical, Waltham, Mass.),[82] i-STAT (i-STAT Abbott Diagnostics, Chicago),[141] and AVL OMNI (Roche Diagnostics Ltd., Lewes, East Sussex, UK) analytical systems. A similar approach has been used to enable real-time monitoring of dialysis efficiency.[74] Alternative enzymatic approaches to the measurement of urea have more recently been described. Morishita et al[143] have described a system incorporating leucine dehydrogenase (EC 1.4.1.9), in addition to urease, which eliminates interference from endogenous ammonium.

The specificity of all of the methods is good, particularly for the urease-glutamate dehydrogenase procedure; however, endogenous ammonia interference must be expected when the protocol employs the sample to initiate the reaction. This may be relevant in aged samples, in some urines, and in particular metabolic disorders. Typically, within-run CVs of less than 3.0% with between-day values of less than 4.0% are achievable in the concentration range of 14 to 20 mg/dL (5 to 7 mmol/L). Given the high intrinsic biological variation of plasma urea, this is well within desired standards of analytical performance.[217]

Other Methods

An improved isotope-dilution MS method for plasma urea measurement has recently been proposed as a reference method.[113] As discussed above, laboratory urea measurements using standard enzymatic techniques are generally of an acceptable quality for most clinical purposes. New approaches to urea measurement are generally targeted at novel clinical applications, including point-of-care testing. For example, Eddy and Arnold[58] have developed a near-infrared spectroscopy technique for measuring urea in hemodialysis fluids. This would facilitate noninvasive monitoring of dialysis efficacy in real time. A novel enzymatic assay described by Naslund et al,[145] using luminometric detection, demonstrates sensitivity, which would make the method suitable for in vivo monitoring studies using microdialysis techniques.

Reference Intervals

The reference interval for plasma urea nitrogen in healthy adults is 6 to 20 mg/dL (2.1 to 7.1 mmol/L expressed as urea).[221] In adults more than 60 years of age, the reference interval is 8 to 23 mg/dL (2.9 to 8.2 mmol/L). Plasma concentrations tend to be slightly lower in children and in pregnancy and slightly higher in males than in females. Plasma urea concentrations in a patient with untreated ESRD typically reach 108 to 135 mg/dL (40.0 to 50.0 mmol/L).

URIC ACID

Biochemistry and Physiology

In humans, uric acid (2,6,8-trihydroxypurine) is the major product of the catabolism of the purine nucleosides adenosine and guanosine (Figure 24-3). Purines from catabolism of dietary nucleic acid are converted to uric acid directly. The bulk of purines excreted as uric acid arise from degradation of endogenous nucleic acids. The daily synthesis rate of uric acid is approximately 400 mg; dietary sources contribute

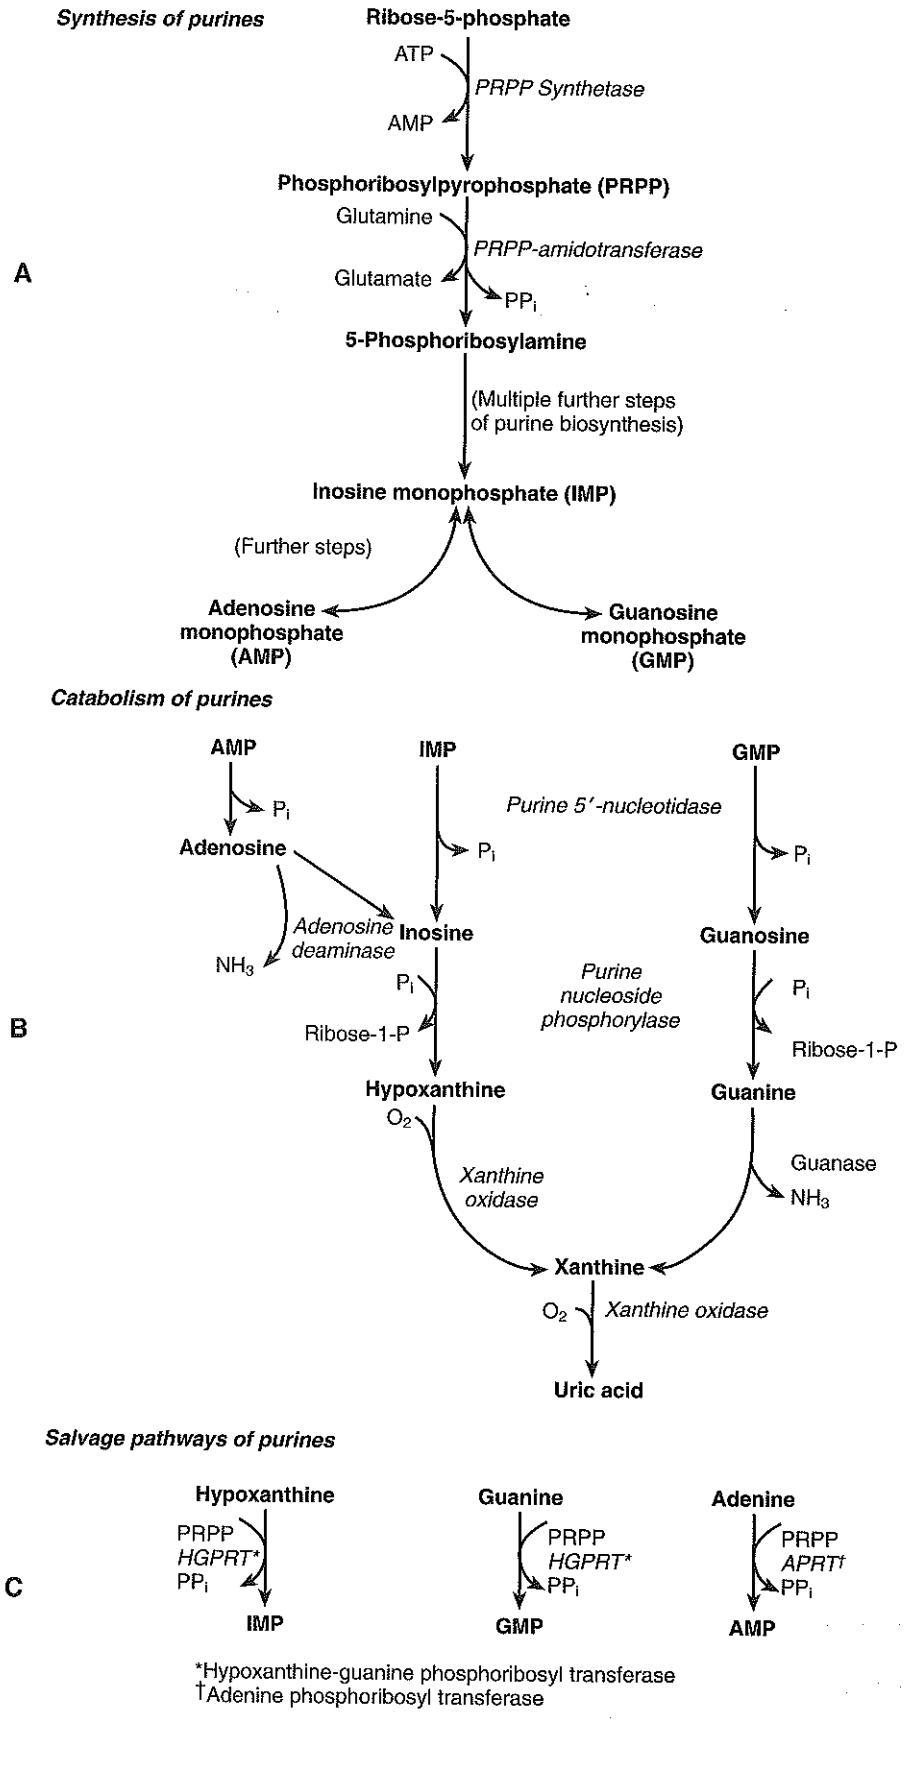


Figure 24-3 Metabolism of purines: **A,** synthesis; **B,** catabolism; and **C,** salvage pathways.

another 300 mg. In men consuming a purine-free diet, the total body pool of exchangeable urate is estimated at 1200 mg; in women it is estimated to be 600 mg. By contrast, patients with gouty arthritis and tissue deposition of urate may have urate pools as large as 18,000 to 30,000 mg.

Overproduction of uric acid may result from increased synthesis of purine precursors. Synthesis and metabolism of the major precursors are illustrated in outline in Figure 24-3. Formation of 5′-phosphoribosylamine is the second enzymatic step in the synthetic pathway (Figure 24-3, *A*); it is the first irreversibly committed step in purine biosynthesis. The intracellular concentration of the substrate phosphoribosylpyrophosphate (PRPP) regulates de novo purine synthesis. The enzyme PRPP-amidotransferase is controlled through feedback inhibition by the purine nucleotides that are the final products of the biosynthetic pathway. The first purine nucleotide formed by ring closure is inosine monophosphate (IMP); adenosine and guanosine monophosphates are derived from IMP through enzymatically mediated interconversions. Adenine and guanine nucleotides may then be used as precursors for the corresponding nucleosides that are the building blocks of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), or, when further phosphorylated, these nucleotides become carriers of high-energy bonds in the form of ATP and guanosine triphosphate (GTP).

Catabolism of the nucleotides (Figure 24-3, *B*) begins with removal of their ribose-linked phosphate, a process catalyzed by purine 5′-nucleotidase. Removal of the ribose moiety of inosine and guanosine by the action of purine-nucleoside phosphorylase forms hypoxanthine and guanine, both of which are converted to xanthine. Xanthine is converted to uric acid through the action of xanthine oxidase.

Reutilization of the major purine bases adenine, hypoxanthine, and guanine, is achieved through "salvage" pathways (Figure 24-3, *C*), in which phosphoribosylation of the free bases causes resynthesis of the respective nucleotide monophosphates. Adenine is converted to adenosine monophosphate (AMP) through the action of adenine phosphoribosyl transferase (APRT), hypoxanthine, and guanine to their monophosphates through hypoxanthine-guanine phosphoribosyl transferase (HGPRT). The HGPRT pathway is quantitatively more important than the APRT pathway.[236]

Lower primates and mammals other than humans carry purine metabolism one step further with the formation of allantoin from uric acid, a step mediated by uricase ([urate: oxygen] oxidoreductase, EC 1.7.3.3). In humans, approximately 75% of uric acid excreted is lost in the urine; most of the remainder is secreted into the gastrointestinal tract, where it is degraded to allantoin and other compounds by bacterial enzymes.

Renal handling of uric acid is complex and involves four sequential steps: (1) glomerular filtration of virtually all the uric acid in capillary plasma entering the glomerulus; (2) reabsorption in the proximal convoluted tubule of about 98% to 100% of filtered uric acid; (3) subsequent secretion of uric acid into the lumen in the distal portion of the proximal tubule; and (4) further reabsorption in the distal tubule. The net urinary excretion of uric acid is 6% to 12% of the amount filtered.

The physicochemical properties of uric acid are important in considering uric acid concentrations in the circulation, in tissue, and in the kidneys. The first pK_a of uric acid is 5.57; above this pH, uric acid exists chiefly as urate ion, which is more soluble than uric acid.[236] At a urine pH below 5.75, uric acid is the predominant form.

Clinical Significance

More than 20 inherited disorders of purine metabolism giving rise to both hypouricemias and hyperuricemias have been recognized to date. Most are very rare and the diagnosis requires support from a specialist purine laboratory. Symptoms that should raise suspicion include kidney failure or stones in a child or young adult; "gravel" in an infant's diaper; unexplained neurological problems in an infant, child, or adolescent; and gout presenting in a man or woman less than 30 years old.

Hyperuricemia

Hyperuricemia is most commonly defined by plasma uric acid concentrations greater than 7.0 mg/dL (0.42 mmol/L) in men or greater than 6.0 mg/dL (0.36 mmol/L) in women. The major causes of hyperuricemia are summarized in Box 24-1. Asymptomatic hyperuricemia is frequently detected through biochemical screening; long-term follow-up of asymptomatic hyperuricemic patients is undertaken because many are at risk for kidney disease that may develop as a result of hyperuricemia and hyperuricuria; few of these patients ever develop the clinical syndrome of gout.[196]

Measurement of plasma uric acid is predominantly used in the investigation of gout, either as a result of a primary hyperuricemia or caused by other conditions or treatments that give rise to secondary hyperuricemias. It is also used in the diagnosis and monitoring of pregnancy-induced hypertension (preeclamptic toxemia).

Gout occurs when monosodium urate precipitates from supersaturated body fluids; the deposits of urate are responsible for the clinical signs and symptoms. Gouty arthritis may be associated with urate crystals in joint fluid and with deposits of crystals (tophi) in tissue surrounding the joint. The deposits may occur in other soft tissue as well, and wherever they occur they elicit an intense inflammatory response consisting of polymorphonuclear leukocytes and macrophages. The big toe (first metatarsophalangeal) joint is the classic site for gout. Gout is a condition characterized by occasional attacks and long periods of remission: it is important to appreciate that the plasma uric acid concentration is often normal during an acute attack. Kidney disease associated with hyperuricemia may take one or more of several forms: (1) gouty nephropathy with urate deposi-

BOX 24-1 Etiology of Hyperuricemia

Increased Formation

Primary

- Idiopathic
- Inherited metabolic disorders

Secondary

- Excess dietary purine intake
- Increased nucleic acid turnover (e.g., leukemia, myeloma, radiotherapy, chemotherapy, trauma)
- Psoriasis
- Altered ATP metabolism
- Tissue hypoxia
- Preeclampsia
- Alcohol

Decreased Excretion

Primary (idiopathic)

Secondary

- Acute or chronic kidney disease
- Increased renal reabsorption
- Reduced secretion
- Lead poisoning
- Preeclampsia
- Organic acids (e.g., lactate and acetoacetate)
- Salicylate (low doses)
- Thiazide diuretics
- Trisomy 21 (Down syndrome)

tion in renal parenchyma, (2) acute intratubular deposition of urate crystals, and (3) urate nephrolithiasis.[34]

Gout is classified as either primary or secondary. *Primary gout* is associated with "essential" hyperuricemia, which has a polygenic basis. In greater than 99% of cases, the cause is uncertain but is probably due to a combination of metabolic overproduction of purines (25% of patients have increased PRPP-amidotransferase activity), decreased renal excretion (80% of patients show decreased renal tubular secretion of uric acid), and increased dietary intake. Very rarely, primary gout is attributable to inherited defects of enzymes in the pathways of purine metabolism. The *Lesch-Nyhan syndrome* is characterized by complete deficiency of HGPRT (EC 2.4.2.8), the major enzyme of the purine salvage pathways. This X-linked genetic disorder is manifested clinically by mental retardation, abnormal muscle movements, and behavioral problems (self-mutilation and pathological aggressiveness). Patients may present in the first weeks of life with symptoms of crystalluria, acute kidney failure, and gout. Hyperuricemia, hyperuricuria, and markedly decreased activities of HGPRT in erythrocytes, fibroblasts, and other cells are present. Intracellular concentrations of PRPP and rates of purine synthesis are increased. Neurological symptoms of this syndrome may be related to decreased availability of purines to the developing brain, which has limited capacity for de novo purine synthesis and therefore relies on the purine salvage pathways to supply it with most of the purine nucleotides it requires. DNA technology has been applied to prenatal diagnosis in the first trimester using chorionic biopsy material. HGPRT assays on cultured fibroblasts obtained by amniocentesis may be used in the second trimester. Partial deficiency of HGPRT (severe X-linked gout) presents in adolescence or early adulthood as early gout, kidney failure, or nephrolithiasis. Increased concentrations of intracellular PRPP production with consequent increased uric acid concentrations can also occur owing to mutations in PRPP synthetase (EC 2.7.6.1.) (phosphoribosyl pyrophosphate synthetase superactivity), which is also inherited as an X-linked recessive trait. An autosomal dominant familial juvenile hyperuricemic nephropathy has also been recognized. Glucose-6-phosphatase deficiency also leads to hyperuricemia as a result of both overproduction and underexcretion of uric acid.

Secondary gout is a result of hyperuricemia attributable to several identifiable causes. Renal retention of uric acid may occur in acute or chronic kidney disease of any type or as a consequence of administration of drugs; diuretics, in particular, are implicated in the latter instance. Organic acidemia caused by increased acetoacetic acid in diabetic ketoacidosis or by lactic acidosis may interfere with tubular secretion of urate. Increased nucleic acid turnover and a consequent increase in catabolism of purines may be encountered in rapid proliferation of tumor cells and in massive destruction of tumor cells on therapy with certain chemotherapeutic agents.

Management of an acute attack of gout generally involves the use of nonsteroidal antiinflammatory drugs (NSAIDs). Patients should be advised to avoid foods that have a high purine content (e.g., liver, kidneys, red meat, and sardines) and drugs that affect urate excretion (thiazide diuretics and salicylates). Specific pharmacological interventions include the use of uricosuric drugs (e.g., probenecid and sulfinpyrazone), which enhance renal excretion of uric acid by blocking the carriers in the tubular cells that mediate reabsorption, or the xanthine oxidase inhibitor allopurinol. Measurement of urinary uric acid excretion is an aid in selecting appropriate treatment in this context. Patients excreting less than 600 mg/day (3.6 mmol/day) of uric acid are candidates for treatment with uricosuric drugs, which are contraindicated in patients with urate stones or kidney failure. Conversely, patients excreting more than 600 mg/day (3.6 mmol/day) are candidates for treatment with allopurinol. The NSAIDs azapropazone and tiaprofenic acid have a uricosuric effect and so have a place in both the long-term and acute management of gout.[201]

Kidney Stones.[56,87] About one in five patients with clinical gout also has urinary tract uric acid stones. Although plasma and urinary uric acid should be measured in stone formers, many uric acid stone formers do not demonstrate either hyperuricuria or hyperuricemia. However, this may reflect the use of reference intervals derived in a purine-rich, westernized society.[190] The etiology of uric acid stone formation also involves the passage of a persistently acid urine with loss

of the postprandial alkaline tide.[34] Undissociated uric acid (pK_a 5.57) is relatively insoluble, whereas urate at pH 7.0 is greater than 10 times more soluble. Thus in patients with urinary pH persistently less than 6.0, normal urinary concentrations of uric acid will produce supersaturation. Measurement of urinary pH throughout the day can be useful.[190] Pure uric acid stones account for approximately 8% of all urinary tract stones and, unlike many of the calcium-containing stones, are radiolucent. Allopurinol is the mainstay of treatment of uric acid stones. Hyperuricuria is also a risk factor for calcium stone formation (see Chapter 45). Consequently, attempts to increase urinary pH with potassium alkali salts may be counterproductive as a result of increased calcium stone formation.

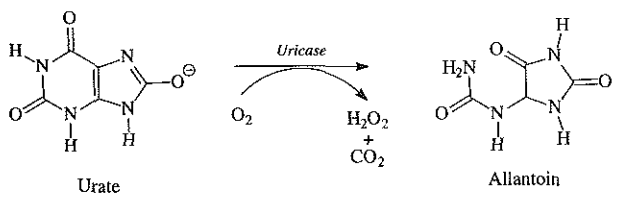
Preeclamptic Toxemia. This condition is associated with increasing plasma uric acid concentration, probably caused by uteroplacental tissue breakdown and decreased kidney perfusion.[62] Plasma urate measurement can be used as an indicator of the severity of preeclampsia. Redman et al[175] noted that concentrations in excess of 6.0 mg/dL (0.36 mmol/L) at 32 weeks gestation are associated with a high perinatal mortality rate.

Hypouricemia

Hypouricemia, often defined as plasma urate concentrations less than 2.0 mg/dL (0.12 mmol/L), is much less common than hyperuricemia. It may be secondary to any one of a number of underlying conditions. Severe hepatocellular disease with reduced purine synthesis or xanthine oxidase activity is one possibility. Another is defective renal tubular reabsorption of uric acid. Defective reabsorption may be congenital, as in generalized Fanconi's syndrome, or acquired. The reabsorption defect may be acquired acutely because of injection of radiopaque contrast media or chronically because of exposure to toxic agents. Overtreatment of hyperuricemia with allopurinol or uricosuric drugs and cancer chemotherapy with 6-mercaptopurine or azathioprine (inhibitors of de novo purine synthesis) may also cause hypouricemia. Very rarely, hypouricemia may occur as a result of an inherited metabolic defect. Hypouricemia in combination with xanthinuria is rarely encountered and suggests a deficiency of xanthine oxidase, either in isolation or as part of combined molybdenum cofactor deficiency (sulfite oxidase/xanthine oxidase deficiency). Purine nucleoside phosphorylase (EC 2.4.2.1) deficiency and other inherited defects have also been described. For further discussion of these, and the primary hyperuricemias, the reader is referred to specialist textbooks.[199]

Analytical Methodology

Phosphotungstic acid (PTA), uricase, and HPLC-based methods have been described for measuring uric acid.[169]



Phosphotungstic Acid Methods

These methods are based on the development of a blue reaction (tungsten blue) as PTA is reduced by urate in an alkaline medium; the color is read by spectrophotometry at wavelengths of 650 to 700 nm. PTA methods are subject to many interferences, and efforts to modify them have had little success in improving their specificity. The reader is referred to a review for a more detailed analysis.[169]

Uricase Methods

Uricase methods are more specific than PTA approaches. Uricase ([urate:oxygen] oxidoreductase; EC 1.7.3.3; main sources *Aspergillus flavus, Candida utilis, Bacillus fastidiosus,* and hog liver) is used either as a single step or as the initial step to oxidize uric acid. Uricase methods became feasible and popular as a result of the availability of high-quality, low-cost preparations of the bacterial enzyme. Preliminary precipitation of protein is not required. Generally, only guanine, xanthine, and a few other structural analogues of uric acid act as alternative substrates, and then only at concentrations improbable in biological fluids. Uricase methods have replaced PTA methods in most current instrumentation.

Uricase acts on uric acid to produce allantoin, hydrogen peroxide, and carbon dioxide.

The reaction can be observed in either the kinetic or the equilibrium mode. The *Bacillus fastidiosus* enzyme has the highest Michaelis constant (1.0×10^{-4} mol/L) and the hog liver has the lowest (1.7×10^{-5} mol/L), the choice of enzyme influencing the incubation period required to reach equilibrium and the conditions for a pseudo first-order kinetic approach. The decrease of absorbance as urate is converted may be monitored by a spectrophotometer at 293 nm and this forms the basis of a proposed reference procedure.[55] However, at this wavelength, most of the absorbance is due to plasma proteins. Therefore there is a high signal-noise ratio, which can compromise the precision of the method. A high quality spectrophotometer with narrow bandpass is required and this is rarely satisfied with automated analyzers.

Most current enzymatic assays for uric acid in plasma involve a peroxidase system coupled with one of a number of oxygen acceptors to produce a chromogen.[106,238] For example, one popular method measures hydrogen peroxide with the aid of horseradish peroxidase (donor:hydrogen-peroxide oxidoreductase; EC 1.11.1.7) and an oxygen acceptor to yield a chromogen in the visible spectrum.[68] Its popularity is probably due to the use of less expensive enzymes and greater analytical sensitivity. The most common oxygen acceptor used is 4-aminophenazone together with phenol or a substituted phenol. The benefit of using substituted phenols is the

enhanced molar absorptivity: phenol ≈ 5.5×10^3 L · mol/cm, tribromo-phenol ≈ 23.6×10^3 L · mol/cm, and tribromo-3-hydroxybenzoic acid ≈ 30.0×10^3 L · mol/cm. Alternative oxygen acceptors include 3-methyl-1-benzothiazoline hydrazone (MBTH), 2,2′-azino-di-(3-ethyl-benzothiazoline)-6-sulfonate (ABTS), and *o*-dianisidine.

Although many combinations of oxygen acceptor and phenol have been described, the choice should be guided by minimization of interference and sufficient absorbance to ensure good precision. The use of a substituted phenol yielding a highly absorbing product helps to reduce the potential interference by reducing the sample volume requirement. The major interferants to minimize are ascorbic acid and bilirubin. In general it is necessary to employ ascorbate oxidase (L-ascorbate:oxygen oxidoreductase; EC 1.10.3.3) in uric acid methodology.[125] Use of aminophenazone with a substituted phenol or the addition of ferrocyanide[68,93] have been used to minimize bilirubin interference. Alternatively, use of the oxygen acceptor azure-D2 (3,7-diamino-5-pheno-thiazine (thionine) derivative), which can be monitored at 600 nm, reduces the spectral but not the chemical[243] interference caused by hyperbilirubinemia.[121] It has also been shown that unknown metabolites in plasma of patients with kidney failure, thought to be phenolic compounds, will interfere by competing with the reagent phenol, giving a low recovery of urate.[100] The interference can be overcome by using a phenolic derivative, thereby generating a higher absorbing product and reducing the sample volume.

Dry Chemistry Systems

Devices that use uricase in a dry reagent format to measure uric acid have also been described. For example, a multilayer film system employs uricase and peroxidase separated by a semipermeable membrane from a leuco dye that is oxidized to form a colored product.[105] A cellulose matrix pad system employs uricase, peroxidase, and MBTH as oxygen acceptor; the system employs a diluted plasma sample, which helps to reduce interferences, although ascorbic acid was shown to be a significant interferant.[107] A third system incorporates separation of plasma from red cells and uricase, peroxidase, and a substituted phenol to measure uric acid.[225] All three systems employ a reflectance meter system to facilitate accurate and precise quantitation of the color change.

Electrochemical and biosensor systems have also been described for the measurement of uric acid. In all cases uricase is employed, being linked in examples to an oxygen electrode[138] and to Teflon on the photomultiplier tube of a luminometer.[80]

HPLC Methods

HPLC methods using ion-exchange or reversed-phase columns have been used to separate and quantify uric acid. The column effluent is monitored at 293 nm to detect the eluting uric acid. HPLC methods are specific and fast, mobile phases are simple, and the retention time for uric acid is less than 6 minutes, reasonable conditions that recommend these methods for reference use.[94] A proposed definitive method for the assay of uric acid in plasma uses isotope-dilution MS.[60]

Reference Intervals

Although many methods for the quantitation of uric acid are described in the literature, the most popular methods today employ the uricase-mediated reaction; however, the specificity of this reaction may be compromised by the choice of detector reaction, owing to either an interfering enzyme or a molecule that competes in the final color generation step. Today reactions that generate a visible end product are preferred because of the higher color yield; however, care should be taken that interference caused by ascorbate, bilirubin, and unspecified interferants in plasma from patients with kidney failure is minimized.

Using an enzymatic method, the reference interval for uric acid has been reported to be 3.5 to 7.2 mg/dL (0.208 to 0.428 mmol/L) for males and 2.6 to 6.0 mg/dL (0.155 to 0.357 mmol/L) for females.[221] The concentration of plasma uric acid increases gradually with age, rising about 10% between the ages of 20 and 60 years. There is a rise in women after menopause, reaching concentrations similar to those in men. During pregnancy, plasma uric acid concentrations fall during the first trimester and until about 24 weeks of gestation, when concentrations begin to rise and eventually exceed nonpregnant concentrations.[36,130] Using an enzymatic assay, reference intervals at 32, 36, and 38 weeks of gestation have been reported as 1.9 to 5.5 mg/dL (0.110 to 0.322 mmol/L), 2.0 to 5.8 mg/dL (0.120 to 0.344 mmol/L), and 2.7 to 6.5 mg/dL (0.157 to 0.381 mmol/L), respectively.[130]

An alternative approach to the interpretation of plasma uric acid concentrations is to consider the degree of hyperuricemia in relation to the risk of developing gout; men with plasma uric acid concentrations exceeding 9.0 mg/dL (0.540 mmol/L) are approximately 150 times more likely to have coexisting gouty arthritis than are men with uric acid concentrations less than 6.0 mg/dL (0.360 mmol/L).[221]

Urinary uric acid excretion in individuals on a diet containing purines is 250 to 750 mg/day (1.5 to 4.5 mmol/day). Excretion may decrease by 20% to 25% on a purine-free diet to less than 400 mg/day.

SCREEENING FOR KIDNEY DISEASE

URINALYSIS

Examination of the urine is often the first step in the assessment of a patient suspected of having, or confirmed to have, deterioration in kidney function. In the laboratory, urine is examined visually, chemically, and microscopically. New instrumental techniques are also being used to examine urine.

Visual Examination

The appearance (color and odor) of urine itself can be helpful, a darkening from the pale normal straw color indi-

cating a more concentrated urine or the presence of another pigment. Hemoglobin and myoglobin can give a pink-red-brown coloration, depending on the concentration. Turbidity in a fresh sample may indicate infection but may also be due to fat particles in a patient with nephrotic syndrome. Excessive foaming of urine when shaken suggests proteinuria. Urine is often chemically evaluated with the help of dipstick tests, which are available for a variety of analytes or microscopically examined.

Dipstick Testing

Many tests of renal significance have been adapted for use on strips of cellulose or pads of cellulose on strips of plastic that have been coated or impregnated with reagents for the analyte in question.[148] This type of analytical test is known as a dipstick test. A dipstick may contain reagents for just one test per stick or reagents for multiple tests on a single stick. For example, up to 10 constituents are now measured on a single dipstick. With this type of test, the different methods detect substances that overflow into the urine, such as glucose, ketones, bilirubin diglucuronate, and urobilinogen, in which changes in the concentration reflect a change in another organ system in the body. These dipstick tests also detect changes in constituents that are more directly linked to alterations brought about by some pathological condition affecting the kidney or urinary tract. Urine samples for dipstick testing should be collected in sterile containers and dipstick testing performed on the fresh urine. Dipsticks should be used only if they have been stored properly desiccated, because they can deteriorate in a matter of hours. Examples of the method principles and comments on the performance of tests pertinent to the assessment of kidney function are given below. In 2003 Clarke and Palmer-Toy[41] have reviewed the literature on outcomes achieved with dipstick urinalysis.

Total Protein

The dipstick test for total protein includes a cellulose test pad impregnated with tetrabromphenol blue and a citrate pH 3 buffer. The reaction is based on the "protein error of indicators" phenomenon in which certain chemical indicators demonstrate one color in the presence of protein and another in its absence. Thus tetrabromphenol blue is green in the presence of protein at pH 3 but yellow in its absence. The color is read after exactly 60 s and the test has a lower detection limit of 150 to 300 mg/L, depending on the type and proportions of protein present. The reagent is most sensitive to albumin and less sensitive to globulins, Bence Jones protein, mucoproteins, and hemoglobin.

Proteinuria is a common finding in patients with kidney disease, and the use of a dipstick assay is an important screening test in any patient suspected of having renal disease. Among patients with suspected or proven CKD, including reflux nephropathy and early glomerulonephritis, and those with hypertension or previously detected asymptomatic hematuria, annual urinalysis for proteinuria is accepted as a useful way of identifying patients at risk of progressive kidney disease. The test has also been used in a number of screening programs in schoolchildren.[140,249] Although these studies have indicated an incidence of about 0.1%, there has been no systematic follow-up of patients to ascertain whether the appearance of protein in the urine is an early predictor of kidney disease.[144] There is currently no proven role for dipstick protein urinalysis in screening of unselected populations.[146,244] Whether it will prove useful in identifying patients at risk of CKD in selected high-risk populations, for instance some ethnic minority populations, remains uncertain. Dipstick testing for proteinuria is inadequate for the detection of CKD among patients with diabetes, who should undergo annual testing for microalbuminuria (see below).

Protein excretion displays considerable biological variability, and may be increased by upright posture, exercise, fever, heart failure, and kidney disease. Because standard urine dipsticks rely on estimation of protein concentration, that in turn depends on hydration or how concentrated the urine sample is; these tests can only give a rough indication of the presence or absence of pathological proteinuria. The specificity of urinalysis protein dipsticks for the detection of proteinuria is approximately 85%[12] and misclassification errors are common. Therefore positive dipstick tests should be confirmed in the laboratory by measuring either the protein/creatinine or albumin/creatinine ratio on an early morning or random urine sample (Figure 24-4). A creatinine test pad (using the peroxidase-like activity of transition metal creatinine complexes) has been added to some strip systems to enable a ratio of protein (or albumin) to creatinine to be reported to reduce the intraindividual variation seen with random urine collections.[150]

Albumin

Dipstick methods are available for the more specific detection of albumin (and also myoglobin and some low molecular weight proteins). Both color-generating and immunological methods for albumin have been described for use with urine samples, the former based on binding of Bis (3′,3″-diiodo-4′,4″-hydroxy-5′,5″-dinitrophenyl)-3,4,5,6-tetrabromosulfonephthalein (DIDNTB) at pH 1.5.[174] The use of the color-generating albumin assay is intended to reduce the variation in reporting of small increases in protein excretion.[174]

Hemoglobin

The presence of hemoglobin in the urine may be due to glomerular, tubulointerstitial, or postrenal disease, although the latter two causes are the more common. The presence of blood in the urine can be detected by the use of a phase contrast microscope to determine the presence of red cells in the urine sediment or by use of a dipstick test. The chemical detection of hemoglobin in urine depends on the peroxidase activity of the protein, employing a peroxide substrate and an oxygen acceptor.[148]

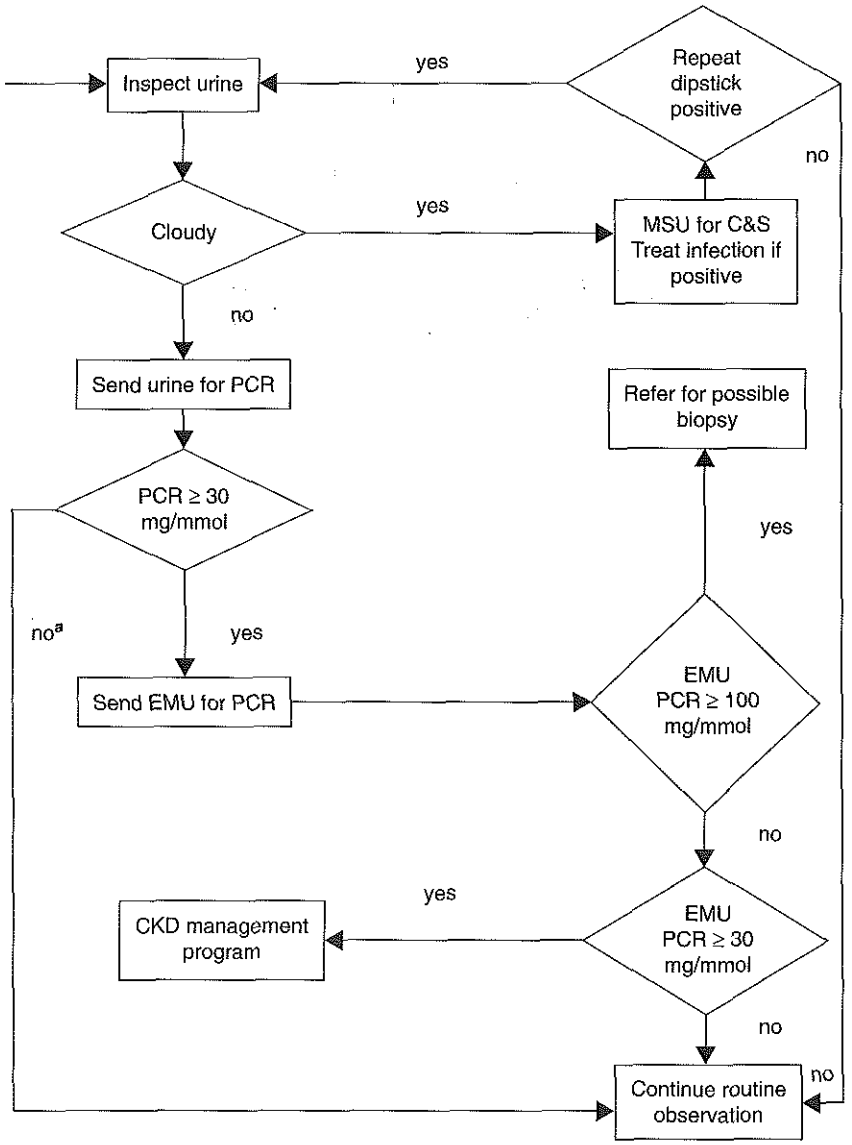


Figure 24-4 Suggested protocol for the further investigation of a positive (trace or above) dipstick or quantitative protein test. Dipstick testing devices show few false-negative results but many false-positive results; positive results should therefore be confirmed using laboratory testing on at least two further occasions. Patients with two or more positive (greater than or equal to 30 mg total protein or albumin/mmole creatinine) tests on early morning samples 1 to 2 weeks apart should be diagnosed as having persistent proteinuria. (The possibility of postural proteinuria should be excluded by the examination of an EMU.) Albumin/creatinine ratio (ACR) measurement can be substituted for the total protein/creatinine ratio. *C&S,* Culture and sensitivity; *CKD,* chronic kidney disease; *EMU,* early morning urine; *MSU,* mid-stream urine; *PCR,* protein/creatinine ratio.
[a]In the absence of a systemic disease, such as diabetes or hypertension, a borderline elevation in total protein or albumin excretion (3 to 30 mg/mmole), without hematuria or a rise in plasma creatinine, a serious primary renal pathology is unlikely. In a diabetic patient, lesser degrees of proteinuria may be significant and should elicit appropriate investigation and management (see "Urinary Albumin and Microalbuminuria Screening" section).
(Algorithm courtesy Dr. R. Burden, Nottingham City Hospital, Nottingham, UK.)

For this test, the reagent pad is impregnated with buffered tetramethyl benzidine (TMB) and an organic peroxide. The method depends on detection of the peroxidase activity of hemoglobin, which catalyzes the reaction of cumene hydroperoxide and TMB. The color change varies from orange through pale to dark green, and red cells or free hemoglobin are detected together with myoglobin. Again the color of the reagent pad should be compared with a color chart after exactly 60 s. Two reagent pads are employed for the low hemoglobin concentration; if intact red cells are present, the low-concentration pad will have a speckled appearance, with a solid color indicating hemolyzed red cells. The detection limit for free hemoglobin is 150 to 600 µg/L or 5 to 20 intact red cells/µL. The test is equally sensitive to hemoglobin and to myoglobin. Water must not be used as a negative control with this test caused by the matrix requirements of the assay, and will give a false-positive result.

The presence of free hemoglobin or red cells in the urine indicates the presence of renal or bladder disease. Hematuria can be present in a number of kidney diseases, including (1) glomerular nephritis, (2) polycystic kidney disease, (3) sickle cell disease, (4) vasculitis, and (5) several infections. A spectrum of urological diseases may also give rise to hematuria, including bladder, prostate, and pelvic and/or ureteral malignancy, kidney stones, trauma, bladder damage, and ureteral stricture.

Glucose

For glucose measurements, the reagent pad is impregnated with glucose oxidase, peroxidase, potassium iodide, and a blue dye. The reaction employs glucose oxidase and peroxidase to produce hydrogen peroxide, which is subsequently reduced with a concurrent oxidation of potassium iodide to release iodine. The free iodine blends with the background color to produce a variety of colors from green to dark

brown. The lower limit of detection for this method is 72 to 127 mg/dL (4.0 to 7.0 mmol/L) with an upper limit of 2018 mg/dL (111 mmol/L). The color change should be read exactly 30 s after sample addition.

Leukocytes

The dipstick test for leukocytes uses an absorbent cellulose pad impregnated with a buffered mixture of derivatized pyrrole amino acid ester and diazonium salt. Granulocytic leukocytes contain esterases that catalyze the hydrolysis of the derivatized pyrrole amino acid ester to liberate 3-hydroxy-5-phenylpyrrole. This pyrrole then reacts with a diazonium salt to produce a purple product. The color of the reagent pad is then compared with the color chart exactly 2 minutes after sample addition. The test is claimed to have a detection limit of 5 to 15 cells/μL in urine and the darkest color block is equivalent to 500 cells/μL or greater. A decrease on the true test result may occur in samples with an elevated glucose concentration, a high specific gravity, or the presence of cephaloxin, cephalothin, tetracycline, or high concentrations of oxalic acid.

Nitrite

To measure nitrite, the reagent pad is impregnated with *p*-arsanilic acid and tetrahydro-benzo(h)quinolin-3-ol. The reaction is based on arsanilic acid in the presence of nitrite converting to a diazonium salt, which couples with the quinolol to produce a pink color. The color should be read exactly 60 s after the sample addition and the detection limit of the test is 61 to 103 μg/dL (13 to 22 μmol/L) nitrite in urine with a normal specific gravity. The test is less sensitive with urine having a high specific gravity. At urine ascorbic acid concentrations above 24.7 mg/dL (1.4 mmol/L) a false-negative result may occur at low nitrite concentrations (81 μg/dL [13 μmol/L] or less). The test will only measure nitrite and is claimed to detect populations of bacteria at an amount of 10^5/mL or more.

The presence of leukocyte esterase is indicative of pyuria. The detection of nitrite is indicative of the presence of bacteria that degrade nitrate excreted in the urine. The combination of the two tests is valuable in patients with urinary tract infection. The absence of both constituents is a valuable test to "rule out" urinary tract infection, thereby reducing the number of samples sent to the laboratory for further tests. The nitrite test may be less helpful in young children in whom the urine remains in the bladder for less time, thereby limiting the time for nitrite production.

Specific Gravity

The test device for specific gravity consists of an absorbent cellulose pad impregnated with bromthymol blue, polymethylvinyl ether and/or maleic anhydride, and sodium hydroxide. The test depends on the apparent pK_a change of the pretreated polyelectrolyte in relation to ionic strength; the hydrogen ions released are detected by the pH indicator. The color changes from a dark blue at a low specific gravity (1.000) to yellow-green at a specific gravity of 1.030. The test is claimed to correlate within 0.005 of refractive index– and hydrometer-derived values; a value of 0.005 can be added to adjust for pH effects above 6.5. In a machine-readable form of the assay (Clinitek System, Bayer Diagnostics, Elkhart, Ind.), automatic adjustment for pH is made (using the data from the pH pad). It is important that the test be read exactly at the time stated (typically 45 s after sample addition). The specific gravity can provide an indication of the concentration of urine; care must be taken with interpretation depending on the method principle because those that detect ionic species will underestimate the specific gravity in the presence of glucose and so forth. Urine collected after intravenous administration of iodine-containing radiopaque compounds for radiological studies may give extraordinarily high values. Glucose and protein may also contribute substantial increments to the density of urine, and semiquantitative determination of these substances is necessary for valid interpretation or correction of urine specific gravity measurements. Diabetic patients with uncontrolled hyperglycemia and glucosuria may have high urine specific gravity even when the normal renal concentrating function is seriously impaired.

pH

To measure the pH of a sample, the test pad is impregnated with indicators—one example being a mixture of methyl red and bromthymol blue. Methyl red in a diluted form is red at pH values below 4.2 and yellow at values above 6.2. Bromthymol blue is yellow at pH values below 6.0 and blue at values above 7.6. At pHs within these values, the indicators give shades of orange and green, respectively. Thus the reagent blocks are evaluated at exactly 60 s and compared with a color chart where the lowest pH block at 5.0 is orange in color and the highest at 8.5 is blue. It is important to recognize that the pH of urine alters with standing and the color of the reagent blocks with time also; therefore careful adherence to the recommended procedure is important. The measurement of urine pH can be helpful in the assessment of patients with renal tubular acidosis and in stone formers, although evaluation using a pH electrode may be more informative.

Microscopic Examination of Urine

Microscopic examination of the sediment obtained from the centrifugation of a fresh urine sample will show the presence of a few cells (erythrocytes, leukocytes, and cells derived from the kidney and urinary tract), casts (composed predominantly of Tamm-Horsfall glycoprotein [THG]), and possibly fat or pigmented particles. An increase in red cells or casts implies hematuria, possibly caused by glomerular disease; white cells or casts imply the presence of white cells in the tubules. Inflammation of the upper urinary tract may result in polymorphonuclear leukocytes and various types of casts, and in lower urinary tract inflammation the casts will not be present. In acute glomerulonephritis, hematuria may

lead to coloration of the urine and the presence of large numbers of red cells and white cells; as the duration of the disease increases, the amount of sediment diminishes.[67]

New Instrumental Techniques

Flow cytometry and flow imaging systems have been developed for the characterization of erythrocytes in the differential diagnosis of hematuria, together with a means of improving the recognition of other particulate material in urine. This form of analysis is now used to both discriminate between and quantify the particulate matter in a defined volume of urine, bringing the added benefit of better standardization of the technique.[157] Thus the flow imaging method can identify red blood cells, white blood cells, white blood cell clumps, hyaline casts, pathological casts, squamous epithelial cells, nonsquamous epithelial cells, yeast, crystals, and sperm. These fully automated systems have the potential to replace urinary microscopy,[247] because they offer better discriminatory power and quantitation while also offering closer agreement between laboratories. The principles of flow cytometry are described in Chapter 3. A flow imaging analyzer such as the Iris iQ200 analyzes unspun urine by aspirating sample through a flow cell positioned in a microscope. A digital camera containing a 1.3 megapixel charge coupled device (CCD) is used to capture the images, and neural network–based particle image recognition software is used to identify and count the particles present from 500, 884 × 680 micrometer fields with 0.68 resolution. The number of particles for the volume scanned is then calculated. The flow image analysis has been shown to be more accurate than the flow cytometric approach while also helping to save valuable technologist time by reducing the number of manual microscopic examinations required.[108,109]

Proton nuclear magnetic resonance (NMR) has also been investigated as a means of characterizing low molecular weight molecules.[147] Metabolic profiles have been generated and, using sophisticated computer analysis, distinctive patterns of molecules have been associated with damage to specific parts of the nephron. It is expected that this technique can be used to identify individual molecules for which selective assays can then be developed.[147]

QUANTITATIVE ASSESSMENT OF GLOMERULAR PERMEABILITY: PROTEINURIA

Clinical Significance

Higher molecular weight proteins are retained within the circulation by the glomerular filter, and lower molecular weight proteins are freely filtered and reabsorbed and catabolized within the tubular cells. Clinically, the appearance of significant amounts of protein in the urine suggests renal disease. Commonly, proteinuria is classified as either tubular or glomerular depending on the pattern of proteinuria observed. A third category, overflow proteinuria, is also recognized in which filtration of excessive amounts of low molecular weight protein exceeds the tubular capacity for reabsorption. Examples of the latter include Bence Jones proteinuria and myoglobinuria. Proteinuria is a potent risk marker for progressive kidney disease, and reduction of protein excretion is a therapeutic target. These aspects are considered further in Chapter 45. This section will consider the analytical approach and rationale used in the quantitation of urinary proteins, with emphasis on total protein and albumin measurement.

Sample Collection for Total Protein and Albumin Measurement

There has been extensive discussion in the literature about the appropriate urine sample to use for the investigation of protein excretion. It is generally recognized that a 24-hour sample is the definitive means of demonstrating the presence of proteinuria. However, overnight, first void in the morning (early morning urine [EMU]), second void in the morning, or random sample collections have also been used. Since creatinine excretion in the urine is fairly constant throughout the 24-hour period, measurement of protein/creatinine (or albumin/creatinine) ratios allows correction for variations in urinary concentration.[16,112] Several authors have recommended the use of the protein/creatinine ratio based on the good correlation that has been demonstrated with the 24-hour collection[40,77,187] and at least equivalent power as a predictor of the rate of loss of GFR in nondiabetic nephropathy.[187] Ginsberg et al studied this in detail and showed that there was little variation in the ratio during the daytime, indicating that the first void and either of the two subsequent collections can give a reliable indication of the 24-hour urine protein excretion. Newman et al[150] demonstrated a significant reduction in the intraindividual variation in the protein/creatinine ratio compared with the protein excretion in random urines collected throughout the day (a mean reduction to 38.6% from 96.5%). They found a similar experience with albumin excretion (52.1% from 80.0%).[150] The ratio to osmolality to correct for dilution effects associated with changes in the water excreted during the day has also been reported and that to specific gravity.[150] Saudan et al[192] found positive and negative predictive values of 95% and 90%, respectively, for the use of the protein/creatinine ratio for detecting proteinuria as defined by a 24-hour collection in hypertensive pregnant women. Dyson[57] found positive and negative predictive values of 81% and 96% in kidney transplant patients, suggesting that the random urine protein/creatinine ratio was a useful screening test for proteinuria. Claudi and Cooper[42] made similar observations on the use of the albumin/creatinine ratio in diabetic patients.

Although the reference point remains the accurately timed 24-hour specimen, it is widely accepted that this is a difficult procedure to control effectively; studies have shown that more than 25% of samples have to be discarded because an incomplete collection is suspected. In practice, for screening purposes, spot urine protein/creatinine ratios (or

albumin/creatinine ratios) have been used to rule out the necessity for 24-hour collections.[146] An EMU sample is preferred since it correlates well with 24-hour protein excretion and is required to exclude the diagnosis of orthostatic (postural) proteinuria.[146] However, a random urine sample is acceptable if no early morning sample is available. If required, daily protein excretion (in mg/24 hours) can be roughly estimated by multiplying the protein/creatinine ratio (measured in mg/mmole) by a factor of 10 since, although daily excretion of creatinine depends on muscle mass, an average figure of 10 mmol creatinine per day can be assumed.[112] In practice, it is accepted that the use of this number will lead to overestimation of daily protein excretion among patients with low muscle mass and underestimation among patients with high muscle mass; in addition, there may be racial variation in creatinine excretion even after adjustment for muscle mass.[135]

A suitable protocol for the further investigation of patients found to have proteinuria at screening is given in Figure 24-4.

Measurement of Total Protein

There are numerous methods used for the measurement of protein in urine (see Chapter 20). They include (1) the original Lowry method,[133] (2) turbidimetry after mixing with trichloroacetic or sulfosalicylic acid,[153] (3) turbidimetry with benzethonium chloride (benzyl dimethyl {2-[2-(*p*-1,1,3,3-tetramethyl butylphenoxy)ethoxy]ethyl} ammonium chloride,[137] (4) dye binding with Coomassie Brilliant Blue,[242] and (5) dye binding with pyrogallol red molybdate.[38]

Concerns about variation in the response to different proteins have led to many variants of the methods being published; this, together with the necessity for automation, resulted in the benzethonium chloride and dye-binding methods becoming the most popular in the United Kingdom.[38] The analytical range of the turbidimetric assays has been of concern, with the equivalent to an "antigen excess" equivalence point being apparent with high protein concentrations giving a lower signal; this can be overcome by monitoring the early period of turbidity formation. The turbidimetric methods and the dye-binding methods do not give equal analytical specificity and sensitivity for all proteins; this may be of particular importance in the detection of light chains, when an immunochemical method is more appropriate. The reactivity of chemical methods to some of the globulins can be enhanced by the inclusion of sodium dodecyl sulfate (SDS) in the reagent.[242] External quality assessment programs have highlighted significant variation between methods (Figure 24-5).[37]

The normal urinary total protein excretion is less than 150 mg/24 hr. The proteins excreted are made up of mostly albumin (50% to 60%) and some smaller proteins, together with proteins secreted by the tubules, of which Tamm-Horsfall glycoprotein (THG) is one. The normal concentrations of proteins found in urine are listed in Table 24-1.

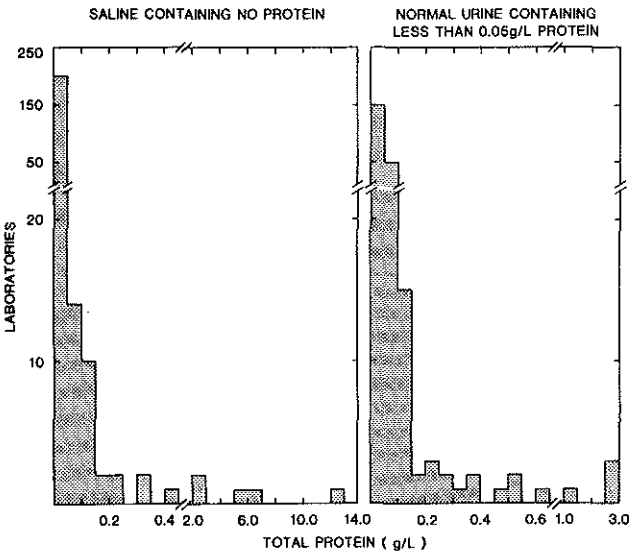

Figure 24-5 Frequency distribution of quantitative results combined with returns of "nil," "zero," or "not detected" for distributions of salt solution and normal urine. Quality control of total protein measurement demonstrates the widespread variation in results achieved using different methods. *(From Chambers RE, Bullock DG, Whicher JT. Urinary total protein estimation: Fact or fiction? Nephron 1989;53:33. Reproduced with permission of S. Karger AG, Basel, Switzerland.)*

Measurement of Individual Proteins

Immunoassay is the preferred method for the accurate and sensitive quantitation of individual proteins (see Chapter 9). Chromatographic and electrophoretic (including capillary electrophoresis) techniques (see Chapters 5 and 6) provide a semiquantitative or qualitative measurement of many of the proteins appearing in the urine and estimations of a panel or pattern of proteins that are not as easily available with the individual assays. The immunoassay techniques include (1) immunodiffusion immunoassay, (2) electroimmunoassay, (3) light-scattering assays with particle enhancement, and (4) labeled immunometric assays (see Chapter 9). However, immunodiffusion and electroimmunoassays require concentration of the urine to detect the low concentrations of protein present, and immunometric assays might require dilution of the sample. The most common approach today for the quantitation of individual urine proteins employs a light-scattering immunoassay, with either turbidimetric or nephelometric detection of immunoaggregate formation.[219,220]

The choice of the type of assay to be used for such measurements depends on the expected concentration of the protein to be measured. For example, in the case of albumin, the assay chosen must be precise at the upper limit of the reference interval (for maximal clinical effectiveness), while also being able to ensure that antigen excess does not occur at high pathological concentrations. In practice, this cannot be achieved in a direct aggregation assay, where the antibody-created particles are aggregated in the presence of

TABLE 24-1 Characteristics of the Major Urinary Proteins

Protein	M_r (kDa)	Free Plasma Concentration (g/L)	Diameter (nm)	pI	Glomerular Sieving Coefficient	Filtered Load (mg/L)†	Urinary Concentration (mg/L)	% Reabsorbed
IgG	150	10	5.5	7.3	0.0001	1	0.1	99
Albumin	66	40	3.5	4.7	0.0002	8	5	99

antigen. Consequently, in this situation, it is better to use a method in which a reagent antigen (in this case, albumin) is coupled to particles. In this instance, the sample antigen inhibits the immunoaggregate formation between antigen-labeled particles and antibody in solution (an immunoinhibition assay). At high sample antigen concentrations, the signal falls to a minimum and then plateaus. Thus "antigen excess" is not a problem, as a dilution has to be performed when this minimum is reached. This method is the preferred approach for the measurement of albumin in urine, where decreased selectivity can lead to a very high albumin excretion rate. The problem does not arise with other proteins, either because the plasma concentration is lower or because the size of the protein inhibits its ready loss into the urine even when permeability increases. More detailed descriptions of light-scattering immunoassays are given in Chapters 9 and 20.

With appropriate sample dilution, the light-scattering immunoassays will provide precise results within an interval of 0.1 mg/L to 20 g/L. Choice of an immunoinhibition assay will ensure that the antigen excess does not lead to an erroneously reported result (see Chapter 9), although sample dilution will be required to give an accurate result at high protein concentration. Values for imprecision of less than ±5% within run and ±8% between runs are attainable over a concentration range of 0.1 mg/L to 20 g/L with the appropriate choice of reaction conditions.

Urinary Albumin and Microalbuminuria Screening

In general, proteinuria reflects albuminuria. Albumin is readily measured by quantitative immunoassay methods capable of detecting urine albumin at low concentrations, and several groups have demonstrated that urinary total protein measurement can be replaced by that of urine albumin.[11,152] This may provide a more specific and sensitive measure of changes in glomerular permeability and is consistent with current national guidelines.[146] However, it should also be noted that changes in albumin excretion may reflect overall changes in vascular permeability and therefore may not indicate an explicit deterioration in renal function.[81]

Dry chemistry systems have also been developed for the quantitation of albumin in urine.[119] For example, in one such device the urine albumin flows laterally along a porous matrix through an area containing gold particle–labeled antibodies to albumin. In the presence of albumin, these antibody molecules are neutralized and pass through a portion of the matrix containing immobilized albumin to a detection zone, where they appear as a pink coloration.[119] The excess labeled antibody is captured by the immobilized albumin. Another device produces a semiquantitative result by diffusing the sample into a gel containing gold sol particle–labeled antibody, the diameter of the ring being proportional to the concentration of the antigen being measured.[116] In another approach for use at the point of care an immunoturbidimetric assay for albumin has been developed in a cassette device with a second reagent encompassing a colorimetric creatinine assay in the same cassette device, enabling semiquantitative reporting of the albumin/creatinine ratio.[159] Photometric assays for both albumin and creatinine have been incorporated in a dual pad dipstick with the reactions being monitored using a reflectance meter.[160]

Microalbuminuria is defined as an increase in urinary excretion of albumin above the reference interval for healthy nondiabetic subjects but at a concentration that is not generally detectable by crude clinical tests, such as dipsticks designed to measure total protein.[52] With improved methodology, these low concentrations of albumin can now be measured, and microalbuminuria is now considered a clinically important indicator of deteriorating renal function in diabetic subjects. For example, it is now accepted by both European and U.S. diabetes societies that regular screening

of urinary albumin excretion is valuable in monitoring both type 1 and type 2 diabetes.* This came as a consequence of the availability of effective treatments, validated in large multinational trials, along with detailed cost-benefit analyses in the vanguard of evidence-based medicine. The U.S. Agency for Health Research and Quality has recently reviewed the literature on increased albumin excretion and risk of renal disease and deteriorating mortality and found that the preponderance of evidence showed that increased albuminuria was associated with an increased risk of renal disease and cardiovascular mortality.[2]

Because of the large numbers of clinical studies that have been performed, there are now well-established guidelines for microalbuminuria screening (Figure 24-6).[5,18,24,206] The diagnosis of microalbuminuria requires the demonstration of increased albumin excretion (either increased albumin/creatinine ratio or increased albumin excretion rate) in at least two out of three urine samples collected in the absence of infection or an acute metabolic crisis. Establishing the diagnosis has both prognostic and management implications in the care of patients with diabetes mellitus. Tight control of diabetes should be achieved before investigating patients for microalbuminuria and patients should not be screened during intercurrent illness. Screening should commence 5 years after diagnosis in patients with type 1 diabetes mellitus and at diagnosis in patients with type 2 diabetes without proteinuria. Screening for microalbuminuria is not indicated in patients with established proteinuria. All other patients with diabetes mellitus should be screened on an annual basis up to the age of 75 years. An early morning (preferred) midstream urine sample should be sent to the laboratory for albumin estimation. An albumin/creatinine ratio less than 23 mg/g (less than 2.5 mg/mmol) in a male or 32 mg/g (less than 3.5 mg/mmol) in a female requires no further investigation until the patient's next annual review. Patients demonstrating albumin/creatinine ratios above, or equal to this cutoff should have urine samples sent to the laboratory on two further occasions (ideally within 1 month) for albumin estimation. Patients demonstrating increased albumin/creatinine ratios in one or both of these further samples have microalbuminuria. It is important to consider other causes of increased albumin excretion, especially in the case of type 1 diabetes present for less than 5 years. These can include nondiabetic renal disease, menstrual contamination, vaginal discharge, uncontrolled hypertension, urinary tract infection, uncontrolled diabetes, heart failure, intercurrent illness, and strenuous exercise. Occasionally, it may be desirable to confirm the diagnosis by measuring the albumin excretion rate in a timed overnight collection; increased albumin excretion in an overnight collection is defined as an overnight albumin excretion rate greater than 20 μg/min.

Once microalbuminuria has been established, an angiotensin converting enzyme (ACE) inhibitor should be prescribed because this class of antihypertensive agent has distinct antiproteinuria effects above and beyond the effects on blood pressure. Several major trials have shown ACE inhibitors to be effective in reducing not just proteinuria but also the rate of fall in GFR when used in both microalbuminuric and proteinuric diabetes. It has even been suggested that ACE inhibitors should be prescribed for normotensive microalbuminuric diabetes, as the definition of normotension as currently used may not reflect the actual intraglomerular pressure, and a lower cutoff should be used in such a high-risk group as diabetics.

It has been suggested that the identification of diabetic patients at risk of developing nephropathy should be attempted earlier than the microalbuminuric stage, when it may already be too late to prevent the development of nephropathy. The use of tubular markers (see below) has been proposed, but as yet none have been shown to provide any more sensitive indications of damage. Considerable work has been undertaken to look for genetic linkages with the development of nephropathy in diabetics. This work has included studies of polymorphisms of the ACE and insulin genes, but as yet no clear relationship has been demonstrated.[194] Other markers of basement membrane damage have also been used to investigate diabetic nephropathy, including urinary excretion of laminin, collagen IV, and fibronectin.[96,172,193] Laminin and collagen IV excretion were found to give no added benefit, but there has been some evidence that urinary fibronectin and metalloproteinase concentrations are elevated before albumin excretion increases.

Bence Jones Proteinuria

The presence of light chains (Bence Jones proteins, 22 kDa) in the urine is an important indication of the presence of myeloma and, in approximately 20% of cases, may occur in the absence of a paraprotein band in the serum (see Chapter 23).[14] The pathological significance of these proteins is considered in more detail in Chapter 45. Although a variety of tests have been used for the detection of Bence Jones protein, including the classic heat test and the Bradshaw test, electrophoresis supplemented by immunofixation is the most reliable approach.[14,237] It is worth noting that the more sensitive systems are capable of detecting low concentrations of protein occasionally associated with benign proliferation of B cells.[14] Quantitation of Bence Jones protein excretion may be required when monitoring patients with light chain–only myeloma. Although imperfect, this is best achieved by electrophoresis and densitometry.[14]

Myoglobinuria

Myoglobin is a small (17.8 kDa), heme-containing protein normally catabolized by endocytosis and proteolysis in the proximal tubule following glomerular filtration. Typically only 0.01% to 5.0% of filtered protein appears in the urine. However, following rhabdomyolysis large amounts of myoglobin are released into the plasma, saturating the tubular

*References 5, 18, 71, 103, 142, 206.

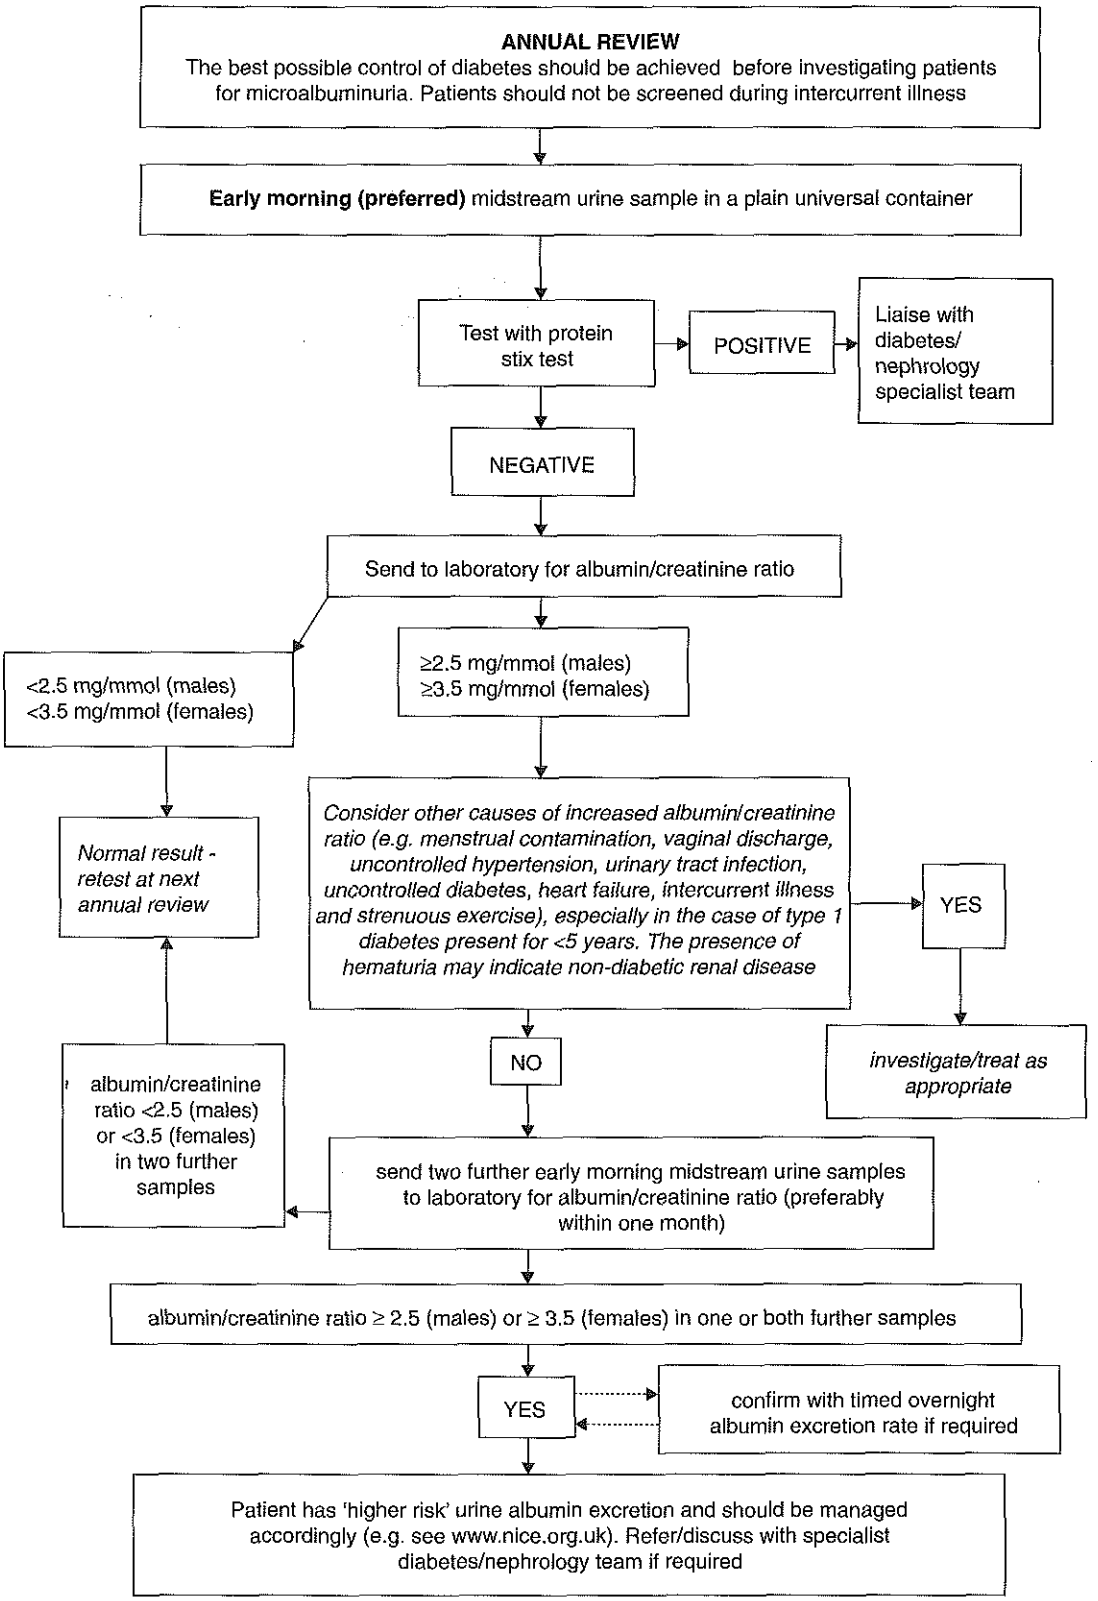

Figure 24-6 Screening for microalbuminuria in diabetes mellitus. Patients demonstrating "higher risk" urine albumin excretion should be managed accordingly. See "Diabetic Renal Disease: Prevention and Early Management" March 2002, available at www.nice.org.uk.

reabsorptive mechanism. This results in the appearance of increased quantities of myoglobin in the urine (which may color the urine red-brown). Further, myoglobin is directly toxic to the renal tubules and can cause acute tubular necrosis with acute renal failure.[251] Myoglobin will give a positive reaction with hemoglobin dipstick tests, and basic methods of detection relied on this principle following removal of hemoglobin (e.g., by ammonium sulfate precipitation), although false-negative and false-positive results are common.[15] Urinary myoglobin is more appropriately measured by immunochemical means, although preconcentration of urine may be required.[132] However, for most purposes evidence that rhabdomyolysis has occurred is better provided by an increase in plasma creatine kinase activity not attributable to a cardiac source. Urinary myoglobin measurement provides no additional prognostic or diagnostic information in this setting.[15]

Tubular Proteinuria

The integrity of the renal tubule can be assessed indirectly through measurement of functional change and detection of tissue damage. The most common approach has been the measurement of urinary concentrations of low molecular weight proteins using immunoassay technology.[17,219] These are freely filtered at the glomerulus and then reabsorbed and catabolized within the proximal tubule. Consequently the appearance of increased quantities of these proteins in the urine reflects failure of the tubular reabsorptive mechanisms. The most commonly measured proteins are retinol binding protein (RBP) and α_1-microglobulin (see Chapters 30 and 20, respectively). Although the excretion of β_2-microglobulin has been extensively studied, it is an impractical marker because of its instability in urine at a pH of less than 6. α_1-microglobulin (Mr 31 kDa) is also referred to as protein HC because of its human complex-forming capacity with IgA. It is synthesized by the liver and the free form is readily filtered at the glomerulus.[234] RBP (Mr 22 kDa) is also synthesized by the liver and is found in the plasma as a complex with prealbumin; the protein is the carrier protein for vitamin A. For the identification of tubular damage, urinary RBP may be more sensitive than α_1-microglobulin, but the higher concentration and excellent stability of the latter in human urine ex vivo facilitate its use as a marker of tubular damage in clinical studies.[104,161] THG, located in the thick ascending limb of the loop of Henle,[91] has also been used as a marker of more distal tubular damage.[163]

Lysozyme is an enzyme that occurs in neutrophilic granulocytes, monocytes, and macrophages, and several organs of the body, including the spleen, kidney, and gastrointestinal tract. It is freely filtered by the kidney and absorbed by the proximal tubules. Thus lysozymuria is seen in conditions associated with both tubular damage and increased endogenous synthesis. Urinary lysozyme is measured by a variety of methods, including catalytic activity and immunoassay; its primary clinical application has been in the monitoring of patients with monocytic leukemia.[156] The reference interval for the excretion of lysozyme in healthy adults is reported to be 1.3 to 3.6 mg/day.[221]

Tubular damage results in the release of intracellular components into the urinary tract, and the measurement of these components reflects the functional integrity of the tubule. A large number of enzymes have been measured in urine.[240] The enzyme *N*-acetyl-β-D-glucosaminidase (NAG) is stable in urine and has been widely used as a marker of tubular integrity. One method for the assay of NAG employs the substrate 4-methylumbelliferyl-N-acetyl-β-D-glucosaminide with a fluorometric measurement of the methylumbelliferone released by the enzyme.[165] Alternative substrates generating products capable of being detected in the visible spectrum have also been described.[250] The measurement of NAG has been undertaken in a variety of diseases associated with renal injury, including hypertension, drug nephrotoxicity, and diabetic nephropathy, as well as transplantation.[171] However, although it is a sensitive marker of kidney damage, it has not generally been shown to provide any unique benefit over other markers of tubular proteinuria. Bazzi et al[13] has demonstrated that urinary NAG could be used to predict progression to renal failure in patients with idiopathic membranous nephropathy. Measurement of α- and π-glutathione-S-transferase (EC 2.5.1.18) isoenzymes has been proposed to discriminate between proximal and distal tubular damage, respectively,[114] but the role of these markers in clinical practice has yet to be established.

Other markers are also available for monitoring the breakdown of the basement membrane components, including collagen breakdown products[96,246] and laminin fragments.[172] However, at present, few of these markers have found a place in the clinical laboratory.

Characterization of Proteinuria

As glomerular damage increases, the permeability of the membrane decreases, with an increasing proportion of higher molecular weight proteins appearing in the urine. The relative clearance of a number of proteins has been measured to assess the selectivity of the membrane and provide an assessment of glomerular damage. The *protein selectivity index* is discussed in the third edition of this textbook, but is generally considered to be of limited value.[33] A commercial semiautomated sodium dodecyl sulfate–agarose gel electrophoresis system (Hydragel, Sebia, France) has been introduced for qualitative analysis of urinary proteins. This separates proteins on the basis of their molecular size, enabling visualization of glomerular, tubular, and mixed patterns of proteinuria. This approach has also been used for the detection and quantitation of Bence Jones proteinuria.[126] Panels of protein measurements, including albumin, α_1-microglobulin, IgG, and α_2-macroglobulin, have been employed in the differential diagnosis of prerenal and postrenal disease.[89] This general strategy was extended with the inclusion of dipstick tests for hematuria, leukocyturia, and proteinuria in the development of an expert

system achieving a concordance of 98% with clinical diagnosis.[95]

ASSESSMENT OF KIDNEY FUNCTION: ESTIMATION OF GLOMERULAR FILTRATION RATE

The GFR is widely accepted as the best overall measure of kidney function, enabling a statement of the complex functions of the kidney in a single numerical expression.[146] A decrease in GFR precedes kidney failure in all forms of progressive disease. Different pathological kidney conditions can progress to ESRD and dialysis dependency at rates varying from weeks to several decades.[32,111,178] The symptoms accompanying progressive kidney disease (see Chapter 45) and their correlation with falling GFR will be influenced by this rate of progression. Measuring GFR in established disease is useful in targeting treatment, monitoring progression, and predicting the point at which renal replacement therapy will be required. It is also used as a guide to dosage of renally excreted drugs to prevent potential drug toxicity. A number of methods are used to measure the GFR; most involve the kidneys' ability to clear either an exogenous or endogenous marker. Improving methodology and the discovery of new markers of GFR and glomerular or tubular damage will continue to provide important contributions to the early diagnosis of renal disease.

The Concept of Clearance

Most of the clinical laboratory information used to assess kidney function is derived from or related to measurement of the clearance of some substance by the kidneys. The renal clearance of a substance is defined as "the volume of plasma from which the substance is completely cleared by the kidneys per unit of time.[131,224] Provided a substance S is in stable concentration in the plasma; is physiologically inert; freely filtered at the glomerulus; and neither secreted, reabsorbed, synthesized, nor metabolized by the kidney, then the amount of that substance filtered at the glomerulus is equal to the amount excreted in the urine (i.e., the amount of S entering the kidney must exactly equal the amount leaving it). The amount of S filtered at the glomerulus = GFR multiplied by plasma S concentration: GFR × PS. The amount of S excreted equals the urine S concentration (US) multiplied by the urinary flow rate (V, volume excreted per unit time).

Since filtered S = excreted S, then

$$\text{GFR} \times P_S = U_S \times V \quad (1)$$

or

$$\text{GFR} = \frac{(U_S \times V)}{P_S} \quad (2)$$

where GFR = *clearance* in units of milliliters of plasma cleared of a substance per minute
U_S = urinary concentration of the substance
V = volumetric flow rate of urine in milliliters per minute
P_S = plasma concentration of the substance

The term $(U_S \times V)/P_S$ is defined as the clearance of substance S and is an accurate estimate of GFR providing the aforementioned criteria are satisfied. Inulin satisfies these criteria and has long been regarded as the most accurate (gold standard) estimate of GFR (see below).

Kidney size and GFR are roughly proportional to body size. It is conventional therefore to adjust clearance estimates to a standard body surface area (BSA) of 1.73 m^2, according to the formula devised by Du Bois and Du Bois in 1916[53]:

$$\text{BSA} = \text{weight (kg)}^{0.425} \times \text{height (cm)}^{0.725} \times 7.1 \times 10^{-3} \quad (3)$$

Markers Used

A variety of exogenous (radioisotopic and nonradioisotopic) and endogenous markers have been used to estimate clearance (Table 24-2). Measurement of clearance may require accurate measurements of both plasma and urinary concentrations of the marker used plus a reliable urine collection. For a reliable plasma measurement, the substance must have reached a steady-state concentration and not be rapidly changing. For a reliable urine collection, the urine flow must be adequate (several mL/min), the collection period of long enough duration, and complete bladder emptying achieved; these requirements are problematic.

Exogenous Markers of Glomerular Filtration Rate

The use of exogenous markers to measure GFR is recommended for the monitoring of slowly progressing nephropathies, such as that associated with diabetes. Exogenous markers are also used to determine a GFR that is used to set a benchmark against which to monitor deterioration in GFR using an endogenous marker, such as creatinine. Measurement of GFR using an exogenous molecule does enable smaller deteriorations in renal function to be observed even when the imprecision in measurement is taken into account.

Both radioisotopic labeled and nonradioisotopic markers are used as exogenous markers. They are administered as a constant infusion or as a single bolus.

Radioisotopic Markers

Radiopharmaceuticals that have been used include (1) ^{51}Cr-EDTA,[7,8,19,30,39] (2) ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA), and (3) ^{125}I-iothalamate. ^{51}Cr-EDTA is preferred to ^{99m}Tc-DTPA and ^{125}I-iothalamate since its clearance is considered to be closest to that of inulin.[20,30] ^{99m}Tc-DTPA has the advantage that it can also be used for gamma camera imaging. ^{125}I-iothalamate is no longer approved for intravascular use in some countries.[20] GFR measurements may be based on either the urinary or plasma clearance of the marker. To ensure accuracy when measuring GFR using urinary clearance methods it is essential that (1) renal

TABLE 24-2 Markers of Glomerular Filtration Rate: Hierarchical Arrangement

Hierarchy	Marker	Advantages	Disadvantages
Gold standard	Inulin (sinistrin) continuous infusion urinary clearance method	Gold standard	Exogenous Time consuming[61] Requires a timed urine collection Poor specificity of analysis Extrarenal clearance = 0.083 mL/min/kg
Silver standard	Inulin (sinistrin) single bolus plasma clearance method		Exogenous Time consuming[61] Poor specificity of analysis Extrarenal clearance = 0.083 mL/min/kg
	^{51}Cr-EDTA	Radioisotopic (simple measurement) Close correlation with inulin clearance[30]	Exogenous Radioisotopic (risks of ionizing radiation) Time consuming[177] Extrarenal clearance = 0.079 mL/min/kg ^{51}Cr less readily available than ^{99m}technetium (Tc)
	^{99m}Tc-DTPA	Radioisotopic (simple measurement) Can be used for gamma camera imaging	Exogenous Radioisotopic (risks of ionizing radiation) Time consuming[59,177] Protein binding
	^{125}I-iothalamate	Radioisotopic (simple measurement)	Exogenous Radioisotopic (risks of ionizing radiation) Not available in all countries Reports of allergic reactions
	Iohexol	Nonradioisotopic	Exogenous Extrarenal clearance[76,118] = 0.087 mL/min/kg Reports of allergic reactions
Bronze standard	Creatinine	Endogenous Inexpensive Can be used to generate GFR from formula (e.g., MDRD)	Poor sensitivity and specificity
	Cystatin C	Not secreted/reabsorbed Constitutively expressed More sensitive and specific than creatinine	Influence of thyroid function[49,72,101]
Of uncertain clinical use	Creatinine clearance	Endogenous Inexpensive	Requires a timed urine collection Inaccurate
	Urea	Endogenous Inexpensive	Poor sensitivity and specificity
	Retinol-binding protein (RBP)	Endogenous Not secreted/reabsorbed	Nonrenal influences on production rate
	α_1-microglobulin	Endogenous Not secreted/reabsorbed	Nonrenal influences on production rate Less freely filtered than RBP

tubular secretion or reabsorption does not contribute to the elimination of the compound, (2) plasma protein binding of the radiopharmaceutical is negligible, and (3) patients completely empty their bladder. ^{99m}Tc-DTPA has been associated with problems of plasma protein binding of the tracer, but more recent formulations have minimized this problem.[20] Plasma clearance of a radionuclide measures GFR reliably only if nonrenal clearance routes are negligible. For research purposes in patients with low (less than 30 mL/min) GFR and in patients with ascites or edema, measurement is best performed using a urinary clearance method.[20] From a clinical management perspective, in the majority of patients, either urinary or plasma clearance approaches are acceptable.

Nonradiosotopic Markers

Nonradioactive compounds used to measure GFR include inulin and iohexol.[59]

Inulin Clearance. The fructose polymer inulin (molecular mass approximately 5 kDa) satisfies the criteria as an ideal marker of GFR. Inulin clearance using a constant infusion urinary clearance approach has long been regarded as the gold standard measure of GFR. Acceptable single bolus plasma clearance approaches have also been evaluated.[227] However, lack of availability of simple laboratory methods of measurement remains an impediment to universal usage. Early methods for the measurement of inulin were based on the hydrolysis of inulin with concentrated sulfuric acid and condensation with anthrone to give a green product that could be read at 620 nm. Later methods were based on the enzyme inulinase (EC 3.2.17), which converts inulin to fructose; the fructose can then be determined with the aid of sorbitol dehydrogenase (EC 1.1.1.14) according to the following reaction sequence[211]:

$$\text{Inulin} \xrightarrow{\text{Inulinase}} \text{Fructose} + \text{NADH} \xrightarrow{\text{Sorbitol Dehydrogenase}} \text{Sorbital} + \text{NAD}$$

The amount of inulin present is determined from the reduction of nicotinamide-adenine dinucleotide, reduced form (NADH) measured as a decrease in absorbance at 340 nm. The method is calibrated with either inulin or fructose; endogenous fructose in each sample is measured by incubation with an inactivated inulinase reagent. Urine samples require predilution (typically 1 in 40) before analysis. A typical between-run imprecision of less than ±2% for plasma and less than ±4% for urine can be obtained with an automated assay.

An alternative method for detecting the fructose produced involves the use of fructokinase (EC 2.7.1.4), phosphoglucose isomerase, and glucose-6-phosphate dehydrogenase (EC 1.1.1.49), measuring in this case the nicotinamide-adenine dinucleotide phosphate, reduced form (NADPH) produced.[167,209]

Iohexol Clearance. The clearance of the nonradioactive x-ray contrast agent iohexol has been proposed as a simpler alternative to inulin clearance.[6,118] In one method, plasma iohexol is measured by HPLC with reversed-phase separation and UV detection, following prior deproteinization with perchloric acid.[118] Analytical imprecision is less than ±3% intraassay and ±5% interassay. Rapid, inexpensive capillary electrophoresis iohexol measurement techniques have also been described.[102,180] Single bolus plasma clearance of iohexol demonstrates excellent agreement with constant infusion urinary inulin clearance.[76] Biological variability in patients with kidney disease using this technique is approximately 6%.[75] Iohexol clearance appears to provide a suitable method of GFR measurement in the setting of diabetic nephropathy.[90] The nonradioisotopic and stable nature of iohexol enables analysis of samples to be delayed and common reference centers to be used for multinational studies. An outpatient procedure based on filter paper blood spots has been described.[51]

Administration

Both constant infusion and single bolus injection methods are used to administer an exogenous marker. In the constant infusion technique, the fasting subject is required to drink 500 mL of water 1 hour before the study begins, after which he or she is required to take 200 mL every half hour until the end of the study. The subject remains supine throughout the study. An intravenous loading dose of the marker selected is then followed by a constant infusion of a given quantity of marker per minute for 3 hours. After equilibration for 1 hour, blood is taken and urine samples are collected at hourly intervals for 3 hours. This technique can be used with any of the exogenous markers, the dosage being all that will vary between molecules. For example, for inulin, an intravenous loading dose of 2.3 g would be followed by a constant infusion of 18.1 mg/min for 3 hours.

Single bolus plasma clearance methods[98] have obvious practical advantages compared with the complex continuous infusion methods. A single dose of the marker (e.g., inulin, 70 mg/kg; iohexol, 5 mL, Omnipaque 300 mg iodine/mL [Nycomed AS, Oslo, Norway]; or ^{51}Cr-EDTA, 50 to 100 μCi) is injected and venous blood samples are then collected at timed intervals (e.g., typically 120, 180, and 240 minutes after the start of the injection for ^{51}Cr-EDTA). The GFR is calculated using knowledge of the amount of marker injected and the decrease in marker concentration (activity) as a function of time. The elimination of the marker is described by a two-compartment model: this comprises an initial equilibration or distribution phase while the marker mixes between the vascular and extravascular space while also being cleared from the plasma by the kidney. The distribution phase can last between 2 and 8 hours, depending on the size of the subject, the distribution volume of the molecule (e.g., longer in edematous patients), and the GFR of the subject (the lower the GFR, the longer the distribution phase). This gives rise to a biexponential clearance curve (Figure 24-7). However, GFR is normally calculated using single-exponential analysis by plotting log marker concentration against time. The half-life is calculated from the slope (k) and the volume of distribution (C_0) of the marker just after injection.

$$\text{GFR} = k \times C_0 \quad (4)$$

Because this model ignores the distribution phase, GFR is overestimated. Various corrections are used to adjust for this (e.g., those proposed by Chantler and Barrett[39] and Brochner-Mortensen[29]). For further details see Blake et al.[19]

Endogenous Markers of Glomerular Filtration Rate

Although the clearance of infused exogenous markers is generally considered an accurate assessment of GFR, to date these procedures have been considered too costly and cumbersome for routine use, particularly where the GFR is

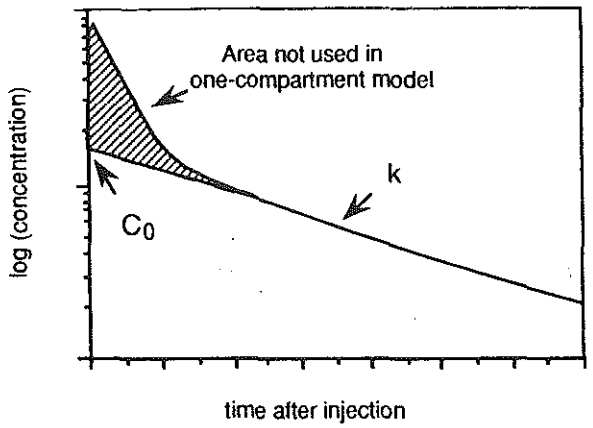

Figure 24-7 Semilog plot used in a single compartmental analysis of the plasma disappearance curve of a GFR marker. In this simplified representation of contrast agent elimination, the distribution phase *(hatched area)* is neglected, which leads to underestimation of the true area under the curve.

assessed on a regular basis (e.g., where patients are receiving nephrotoxic drugs). Creatinine and certain low molecular weight proteins such as cystatin C have been used as endogenous markers of GFR. The use of urea in this context is of limited value[214] and will not be discussed further. Endogenous markers obviate the necessity for injection and require only a single blood sample, simplifying the procedure for the patient, clinician, and laboratory.

Creatinine Concentration

The most widely used endogenous marker of GFR is creatinine, expressed either as its plasma concentration or its renal clearance. The use of creatinine as a marker of GFR was developed in 1926 by Rehberg,[176] who used exogenously administered creatinine. This led to the work of Popper and Mandel,[166] who in 1937 developed the use of endogenous creatinine clearance.

Creatinine (molecular mass 113 Da) is freely filtered at the glomerulus and its concentration is inversely related to GFR. As a GFR marker, it is convenient and cheap to measure but is affected by age, sex, exercise, certain drugs (e.g., cimetidine,[223] trimethoprim), muscle mass, nutritional status, and meat intake.[164,205] Further, a small (but significant) and variable proportion of the creatinine appearing in the urine is derived from tubular secretion. Typically, 7% to 10% is due to tubular secretion,[139] but this is increased in the presence of renal insufficiency. As previously discussed, significant analytical interferences continue to be a problem.[117,205] Perhaps most importantly, plasma creatinine remains within the reference interval until significant renal function has been lost (Figure 24-8).[164] Since plasma creatinine is derived from creatine and phosphocreatine breakdown in muscle, the reference interval encompasses the range of muscle mass observed in the population. This contributes to the insensitivity of creatinine as a marker of diminished GFR. Additionally, in patients with CKD, extrarenal clearance of

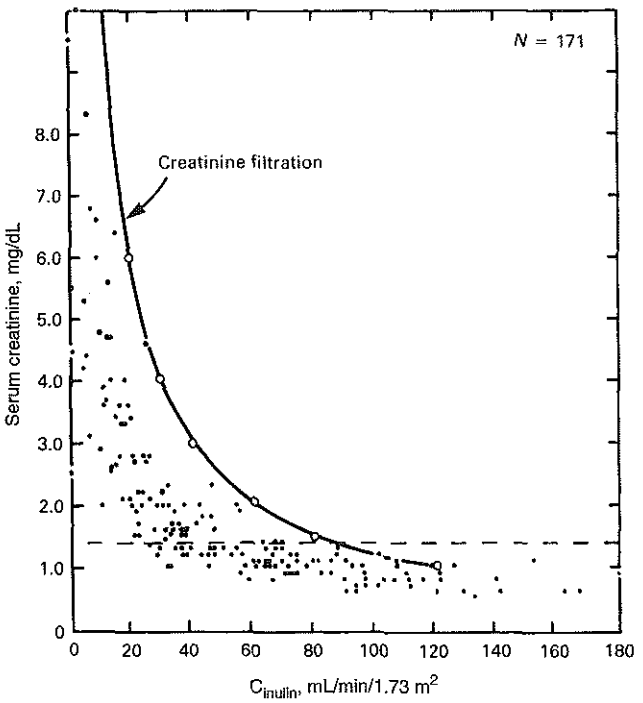

Figure 24-8 The relationship between serum creatinine concentration and GFR, measured as the clearance of inulin, in 171 patients with glomerular disease. The hypothetical relationship between GFR and serum creatinine *is shown as a continuous line*, assuming that only filtration of creatinine takes place. The *dashed horizontal line* represents the upper limit of a normal serum creatinine (1.4 mg/dL). Because of creatinine secretion and/or a creatinine deficit through gut excretion, the serum creatinine consistently overestimates the GFR. *(From Shemesh O, Golbetz H, Kriss JP, Myers BD. Limitations of creatinine as a filtration marker in glomerulopathic patients. Kidney Int 1985;28:830.)*

creatinine further blunts the anticipated increase in plasma creatinine in response to falling GFR.[146] Consequently, plasma creatinine measurement will not detect patients with stage 2 CKD (GFR 60 to 89 mL/min/1.73 m^2) and will also fail to identify many patients with stage 3 CKD (GFR 30 to 59 mL/min/1.73 m^2). Thus although an elevated plasma creatinine concentration does generally equate with impaired kidney function, a normal plasma creatinine does not necessarily equate with normal kidney function. Because of all these limitations, it is recommended that plasma creatinine measurement alone is not used to assess kidney function.[146]

Creatinine Clearance

Because creatinine is endogenously produced and released into body fluids at a constant rate, its clearance has been measured as an indicator of GFR.[164] A protocol for the conduct of the creatinine clearance test may be found in the third edition of this textbook.

Utility. Historically, creatinine clearance has been seen as more sensitive for detection of renal dysfunction than measuring plasma creatinine. However, it requires a timed urine

collection, which introduces its own inaccuracies,[78,162,179] is inconvenient, and is unpleasant. In adults the intraindividual day-to-day CV for repeated measures of creatinine clearance exceeds 25%.[31] Although tubular secretion undermines the theoretical value of creatinine as a marker of GFR, in the context of creatinine clearance this has previously been offset to some extent by the use of nonspecific methods to measure plasma creatinine, which lead to an overestimation of plasma concentration. Nevertheless, creatinine clearance usually equals or exceeds inulin GFR in adults by a factor of 10% to 40% at clearances above 80 mL/min. However, as GFR falls, plasma creatinine rises disproportionately and the creatinine clearance can reach nearly twice that of inulin.[230] Tubular reabsorption of creatinine has also been reported at low GFRs but may represent diffusion of creatinine through gap junctions between tubular cells or directly through the tubular epithelial cells, down a concentration gradient.[164] Whatever the mechanism, this further devalues the use of creatinine clearance. Hence, at best creatinine clearance can only provide a crude index of GFR.

Calculated Clearance. The mathematical relationship between plasma creatinine and GFR can be improved by correcting for the confounding variables that make that relationship nonlinear. More than 25 different formulas have been derived that estimate GFR using plasma creatinine corrected for some or all of gender, body size, race, and age.[146] These may produce a better estimate of GFR than serum creatinine alone. Indeed the National Kidney Foundation of the United States[146] has recommended that such estimates should be used in preference to serum creatinine, and that either the Cockcroft and Gault or Modification of Diet in Renal Disease (MDRD) formula should be used in adults. The Schwartz[195] and Counahan-Barratt[48] formulas are recommended for use in children.

The Cockcroft and Gault[43] formula is one of the earliest, and perhaps most widely used, of these formulas. The authors measured creatinine clearance in more than 200 patients and used regression analysis to enable prediction of creatinine clearance from the serum creatinine concentration, taking age and patient weight into consideration:

$$\text{Creatinine clearance (mL/min)} = \frac{[(140 - \text{age(years)}) \times \text{weight (kg)}]}{72 \times \text{plasma creatinine (mg/dL)}}$$

or

$$\text{Creatinine clearance (mL/min)} = \frac{[(140 - \text{age(years)}) \times \text{weight (kg)}]}{0.814 \times \text{plasma creatinine (}\mu\text{mol/L)}}$$

It should be noted that the formula predicts creatinine clearance, not GFR, and that the results are not corrected for BSA. The formula has become embedded in the medical literature and practice (e.g., aminoglycoside dosage charts have been based upon this estimate of GFR).[191] However, some studies have suggested that it diverges widely from true measures of GFR in certain clinical situations.[164,181] There are also theoretical objections to its use. It was derived among a population only 4% of whom were female: an arbitrary correction factor of 0.85 was recommended for females.[43] A relatively nonspecific Jaffe method was used for measuring plasma creatinine; transferability of data to enzymatic creatinine methods, for example, may not be appropriate. Nevertheless, when compared against exogenous clearance marker methods, subsequent experience has generally shown that the formula produces more accurate and precise estimates of GFR than measured creatinine clearance.[47,122,146,230] An example of the agreement between predicted creatinine clearance and GFR can be seen in Figure 24-9.[47]

In 1999 Levey et al[128] proposed a formula that also included plasma urea and albumin concentrations and race

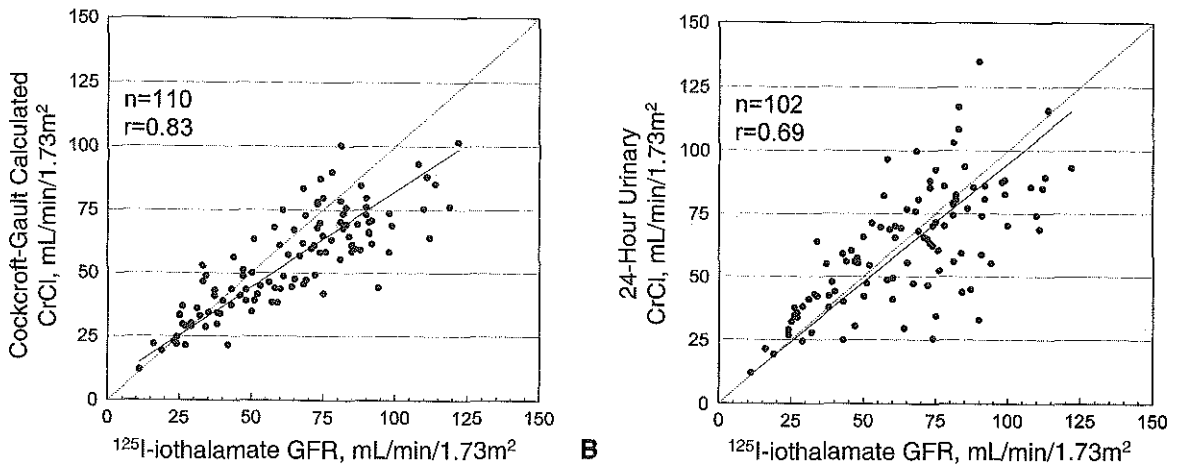

Figure 24-9 Relationship between GFR measured using ^{125}I-iothalamate clearance and estimates of creatinine clearance (CrCl) obtained using the **(A)** Cockcroft and Gault equation and **(B)** measured creatinine clearance. *(From Coresh J, Toto RD, Kirk KA, Whelton PK, Massry S, Jones C, et al. Creatinine clearance as a measure of GFR in screenees for the African-American study of kidney disease and hypertension pilot study. Am J Kidney Dis 1998;32:32-42.)*

as covariables. The formula was developed in 1628 predominantly middle-aged patients enrolled in the MDRD study, which is a study of chronic renal insufficiency, and hence is commonly known as the MDRD formula. Plasma urea was found to be an independent predictor of GFR, probably reflecting the differing renal handling of urea and creatinine by the kidney, and also to improve the strength of relationship between creatinine and GFR, possibly by correcting for the effects of catabolism on plasma creatinine. In addition to urea, they also observed that albumin was an independent predictor of GFR, probably reflecting the known relationship between protein intake and renal function.

$$\begin{aligned}\text{GFR}\,(\text{mL/min/1.73 m}^2) = 170 \\ \times [\text{plasma creatinine (mg/dL)}]^{-0.999} \\ \times [\text{age}]^{-0.176} \\ \times [\text{plasma urea nitrogen (mg/dL)}]^{-0.170} \\ \times [\text{plasma albumin (g/dL)}]^{0.318} \\ \times [0.762 \text{ if patient is female}] \\ \times [1.180 \text{ if patient is black}].\end{aligned}$$

or

$$\begin{aligned}\text{GFR}\,(\text{mL/min/1.73 m}^2) = 170 \\ \times [\text{plasma creatinine } (\mu\text{mol/L}) \times 0.011312]^{-0.999} \\ \times [\text{age}]^{-0.176} \\ \times [\text{plasma urea (mmol/L)} \times 2.801]^{-0.170} \\ \times [\text{plasma albumin (g/L)} \times 0.1]^{+0.318} \\ \times [0.762 \text{ if patient is female}] \\ \times [1.180 \text{ if patient is black}]\end{aligned}$$

These workers have subsequently also published, in abstract form, an abbreviated version of this formula, which does not require albumin or urea.[129]

$$\begin{aligned}\text{GFR}\,(\text{mL/min/1.73 m}^2) = 186 \\ \times [\text{plasma creatinine (mg/dL)}]^{-1.154} \\ \times [\text{age}]^{-0.203} \\ \times [0.742 \text{ if patient is female}] \\ \times [1.210 \text{ if patient is black}]\end{aligned}$$

or

$$\begin{aligned}\text{GFR}\,(\text{mL/min/1.73 m}^2) = 186 \\ \times [\text{plasma creatinine } (\mu\text{mol/L}) \times 0.011312]^{-1.154} \\ \times [\text{age}]^{-0.203} \\ \times [0.742 \text{ if patient is female}] \\ \times [1.210 \text{ if patient is black}]\end{aligned}$$

They observed that the MDRD equation provided more accurate assessment of GFR than either the Cockcroft and Gault equation or measured creatinine clearance. The MDRD formula has several advantages: (1) it was developed and validated in a large population, (2) it was developed with a population that included both European-Americans and African-Americans, (3) it does not require patient weight, (4) it was validated against an iothalamate clearance estimate of GFR, and (5) the reported GFR is corrected for BSA. However, the MDRD calculations are more complex than the Cockcroft and Gault equation (e.g., some laboratory data systems are unable to compute power calculations) and there has to date been only limited evaluation of this formula, particularly in certain patient groups (e.g., Asians with kidney disease).

Plasma creatinine is an imperfect marker of GFR and therefore it is not altogether surprising that formulas based predominantly upon it are imperfect. Their use cannot circumvent the very significant spectral interferences affecting plasma creatinine measurement (i.e., hemolysis, icterus, and lipemia) and the formulas are unsuitable for use in patients with acute renal failure, in whom plasma creatinine concentrations are changing rapidly. Additionally, the formulas are critically susceptible to variations in creatinine assay calibration and specificity.[46,245] Notwithstanding the MDRD formula is thought to improve the estimation of GFR compared with plasma creatinine alone.

Low Molecular Weight Proteins

A number of proteins with molecular weights of less than 30 kDa are mostly cleared from the circulation by renal filtration and can be considered to be relatively freely filtered at the glomerular filtration barrier. These include α_2-microglobulin, RBP, α_1-microglobulin, β-trace protein,[173] and cystatin C. These proteins are filtered at the glomerulus, then reabsorbed (and metabolized) in the proximal tubule or excreted into the urine, and thus they are entirely eliminated from the circulation. Therefore they have the potential to meet the criteria for use as a marker of GFR. However, apart from cystatin C, all the other proteins have been shown to have plasma concentrations that are influenced by other, nonrenal factors, such as inflammation (α_2-microglobulin) and liver disease (RBP, α_1-microglobulin).[9] The relationship between the circulating concentrations of these proteins shows the same curvilinear form as plasma creatinine, but very recently several groups have demonstrated that cystatin C measurement may offer a more sensitive and specific means of monitoring changes in GFR than plasma creatinine.[64,84,120,151]

Cystatin C

Cystatin C is a low molecular weight (12.8 kDa) protein synthesized by all nucleated cells whose physiological role is that of a cysteine protease inhibitor.[149] With regard to renal function, its most important attributes are its small size and high isoelectric point (pI = 9.2), which enable it to be more freely filtered than the above-mentioned proteins at the glomerulus.[84] The gene has been sequenced, and the promoter region has been identified as of the housekeeping type, with no known regulatory elements. Consequently the production rate of cystatin C has always been considered to be constant,[1] although several publications suggest an influence of thyroid hormone.[49,72,101] Plasma concentrations of cystatin C appear to be unaffected by muscle mass, diet, or

gender.[120] There are no known extrarenal routes of elimination, with clearance from the circulation only by glomerular filtration.[84,99,218]

Cystatin C has been measured by immunodiffusion or rocket electroimmunoassay, but the methods are too insensitive, and any form of labeled immunometric assay is too cumbersome and time consuming for the response time required. The most practical approaches described are to use a latex particle–enhanced turbidimetric or nephelometric immunoassay. An intraassay precision of less than ±3% can be expected at the upper limit of the reference interval (~1.00 mg/L), with less than ±4% for the between-day value.[64,120,151,208] Further, cystatin C measurement appears unaffected by the spectral interferences affecting creatinine assays.[208]

There are a number of reports documenting the correlation between plasma cystatin C and creatinine (as a reciprocal), and GFR as assessed by ^{51}Cr-EDTA clearance or using a number of alternative exogenous markers. The correlations vary between 0.32 and 0.88 for cystatin C and 0.25 and 0.89 in the case of creatinine. In almost all of the cases the correlation with cystatin C is superior to that with creatinine.[168] Kyhse-Andersen et al[120] first demonstrated, using receiver operator analysis, the superiority of cystatin C measurement compared with creatinine for the detection of kidney disease (Figure 24-10) and this has been confirmed by a 2002 meta-analysis.[50] A 2002 summary receiver operator curve analysis of all of the studies at the time of publication showed an area under the curve of 0.95 for cystatin C and 0.91 for creatinine ($p = 0.003$).[123] Perhaps more critically, Newman et al found that, in a group of patients with a range of GFRs, the cystatin C concentration increased sooner than creatinine as GFR declined; cystatin C concentration started to increase as GFR fell below about 80 mL/min/1.73 m^2 compared with about 40 mL/min/1.73 m^2 for serum creatinine.[151] Cystatin C is therefore especially useful when trying to detect mild to moderate impairment of kidney function.[26,44]

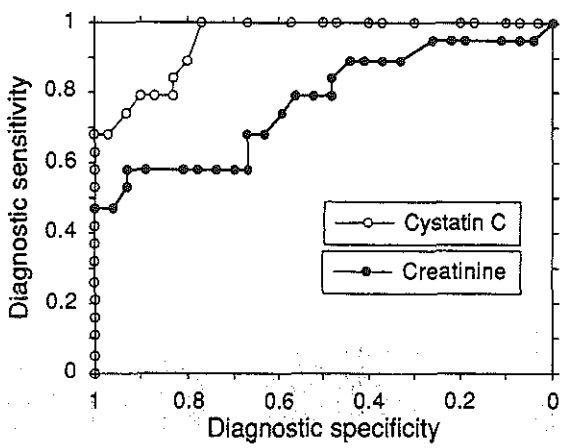

Figure 24-10 Receiver operating characteristic (ROC) curves comparing creatinine and cystatin C in the assessment of GFR. Nonparametric ROC plots were constructed to assess the diagnostic accuracy of serum concentrations of cystatin C and creatinine in distinguishing between normal and reduced GFR (less than 80 mL/min per 1.73 m^2) in 51 patients with various renal conditions. *(From Kyhse-Andersen J, Schmidt C, Nordin G, et al. Serum cystatin C, determined by a rapid, automated particle-enhanced turbidimetric method, is a better marker than serum creatinine for glomerular filtration rate. Clin Chem 1994;40:1921-6.)*

Glomerular Filtration Rate at the Extremes of Age

As discussed previously in this chapter, current markers of GFR are imperfect and the limitations of these tests are accentuated in both pediatric and older populations. At birth, plasma creatinine concentrations approximate those of the maternal circulation. Plasma creatinine concentrations fall rapidly during the neonatal period, with slower falls being observed in premature infants.[186] Plasma creatinine concentrations are lower in infants than in adults, despite their lower GFR, reflecting the lower muscle mass (decreased creatinine production rate). In the setting of pediatric intensive care medicine, the usefulness of plasma creatinine may be further limited by analytical interferences caused by high concentrations of bilirubin and competition with creatinine for tubular secretion by commonly used antibiotics (e.g., trimethoprim and cimetidine). By contrast, plasma cystatin C concentrations in infants appear to more closely reflect GFR, being increased in the first 3 months of life and then falling to approximate adult concentrations by age 1 year (Figure 24-11).[23,65] Further, the diagnostic accuracy of cystatin C for reduced GFR is superior to that of creatinine in children.[86,248]

Plasma creatinine concentrations in healthy older people are not dissimilar to those in younger people, except in nonagenarians and centenarians, despite the decrease in GFR that occurs, on average, with aging.[222] Possible reasons for this include reduced muscle mass and poorer nutrition. Whatever the reason, the same concentration of plasma creatinine may indicate very different degrees of kidney function in younger and older people, and a normal plasma creatinine concentration does not exclude significant renal impairment. The effects of this may be marked and are commonly not appreciated. For example, for a 70-kg man with a plasma creatinine of 1.4 mg/dL (120 μmol/L), the Cockcroft and Gault formula predicts GFRs of 81 and 44 mL/min at age 30 and 80 years, respectively. In two large primary care studies,[54,215] Cockcroft and Gault estimated that GFRs less than 50 mL/min were common in patients with normal plasma creatinine. This was most pronounced in older age groups (e.g., discordance between normal serum creatinine and reduced GFR was observed in 47% of patients aged greater than or equal to 70 years, compared with 1.2% of patients aged 40 to 59 years,[54] and the clinical sensitivity of plasma creatinine for detecting severely reduced GFR [less than 30 mL/min/1.73 m^2] was only 46%).[215] As observed in children, plasma cystatin C, however, does appear to reflect the age-related decline in kidney function[63,231] and appears to be more sensitive than plasma creatinine for detection of reduced GFR.[66,155]

Recommendations and Reference Intervals

The measurement of the urinary clearance of inulin, after continuous infusion, is considered the primary or reference method for the determination of GFR. However, because the necessary plasma and urine assays for inulin often are not practical in clinical laboratories, plasma creatinine or creatinine clearance has almost universally been used for assessment of GFR. With increasing recognition of the importance of early detection and management of CKD, the requirement for more accurate assessment of GFR is being emphasized.[146] Consequently creatinine clearance is no longer considered acceptable as a measure of GFR and plasma creatinine measurements should not be reported in isolation but should be used to generate formulaic estimations of GFR.[146]

In practice, there may be little to choose between the Cockcroft and Gault formula and the more recently described MDRD equation,[22,27,85] and which is chosen will be

influenced by local factors (e.g., interfaces between laboratory and clinical data systems). The susceptibility of these formulas to creatinine assay calibration variations must be recognized and, in this sense, the use of cystatin C, which can be reliably and simply measured on a single blood sample with no requirement for anthropomorphic adjustment, may be advantageous. The success of alternative markers such as cystatin C will depend on understanding the benefit of the superior diagnostic efficacy and improved clinical and economic outcomes in relation to the greater cost of the assay when compared with the Jaffe creatinine methods. However, although all of these markers are an improvement over plasma creatinine and creatinine clearance estimation, they are all only approximate measures of true GFR. Obviously, research into new and more accurate methods of estimating GFR is still required. Table 24-3 provides some reference data for GFR using a variety of methods.
